Having found that Edison had made and used paper-carbon conductors for electric lamps, and had decided that carbon had the requisite qualities of high resist- and small mass necessary to develop his theory.

4. In determining that Edison did not, in fact, invent his paper-carbon conductors until such time subsequently as he had ascertained from experiment the best size for his filaments and had advised a better mode of creating a vacuum in his lamps.

5. In determining that Sawyer and Man did not make the
3603 invention when their lamp had a life of a few minutes, but
did make it when their lamp had a life of a few hours.

6. In determining that the letters and book of Sawyer were not proof of abandonment of the invention of Sawyer and Man, because there was proof that Sawyer and Man had completed the invention before the letters were written.

7. In determining, in effect, that one of two joint inventors cannot abandon the common invention by public declarations known to and uncontradicted by the other inventor.

As to Matter of Fact.

The case finding on uncontradicted testimony that the paper conductors of Edison had a resistance of one hundred ohms, and those of Saw-er and Man a resistance of one-fourth of an ohm.

1. In determining that these conductors were "substantially alike."

The case finding that Edison conductors were simply carbonized paper, where the paper gave the high electrical resistance and the consequent light, and Sawyer and Man's conductors were paper carbons built up by hydrocarbon deposits, where the deposits alone caused the low resistance, and alone gave the light.

2. In determining that these two conductors were "substantially alike."

3. In determining from the proof that Sawyer and Man invented paper-carbon conductors for incandescent lamps in 1878.

3604 4. In determining from the proofs that Edison invented paper-carbon conductors for incandescent lamps in 1879.

5. In determining that Sawyer and Man's paper carbons were perfected inventions.

6. In awarding priority of invention to Sawyer and Man contrary to the proofs in the case.

7. In not awarding priority of invention to Edison, in accordance with the proofs in the case.

As Additional Error of Law.

The issue having been declared by the Patent Office to be "the incandescent conductor for an electric lamp formed of carbonized paper;" and the Commissioner having found that such a conductor was first made, operated and used by Edison in a lamp from which the air had been exhausted with knowledge of its utility and value for incandescent lamps.

In determining that the specific invention in interference was not complete in a legal sense until the other parts and conditions of an incandescent lamp had been perfected, and a lamp produced which would last for hours, weeks and days.

As Additional Error of Fact.

If it be the law that the invention in interference was not complete until such time as it was embodied in a practical and commercial lamp, then the Commissioner erred in determining from the proofs that such a lamp was first made by Sawyer and Man.

DEPARTMENT OF THE INTERIOR,
UNITED STATES PATENT OFFICE,
WASHINGTON, D. C., *Dec.* 26, 1884.

In the Matter of the Interference of SAWYER AND MAN *vs.* EDISON. } Motion for Rehearing.

SIR: You are hereby informed that a hearing on the above motion is fixed for Wednesday, December 31st, 1884, at 10 o'clock a. m.

By direction of the Commissioner.

Very respectfully, SCHUYLER DURYEE,
Chief Clerk.

Sawyer and Man, care Amos Broadnax, 10 Pine St., N. Y. city;
T. A. Edison, care Geo. W. Dyer, present.

(Endorsed: Sawyer and Man *vs.* Edison; notice of hearing; dated Dec. 26, 1884.)

3606 U. S. Patent Office.

EDISON
vs. } Motion for Rehearing.
SAWYER AND MAN.

Incandescent conductor.

Application of T. A. Edison, filed February 11, 1879.

Application of Sawyer and Man, filed Jan. 9, 1880.

Mr. J. C. Tomlinson and R. N. Dyer for Edison.
Mr. A. Broadnax for Sawyer and Man.

This interference was declared for the purpose of deciding which of the contesting parties is entitled to priority for the invention of

The incandescent conductor for an electric lamp formed of carbonized paper.

The examiner of interferences decided in favor of Sawyer and Man. The examiners-in-chief reversed that decision. Mr. Commissioner Marble on appeal reversed the decision of the examiners-in-chief and awarded priority of invention to Sawyer and Man. Edison then appealed to the Secretary of the Interior who heard the case, but, without deciding it, dismissed the appeal under the decision of the Supreme Court of the United States in Butterworth *vs.* Hoe, *et al.* (29 O. G. 615) the Secretary holding that in view of said decision he had no jurisdiction.

Edison now moves for a rehearing before the Commissioner, on the ground that the decision was against the law and weight of the evidence, and I am asked on an inspection of the record to grant a rehearing.

No additional evidence is produced or offered. If there be error, therefore, which can authorize or require the exercise of the jurisdiction invoked, it is apparent on the face of the record itself.

3607 I shall not attempt to consider at length the several points made by counsel, for after all the whole thing may be summed up in the single proposition heretofore mentioned—that the finding of Commissioner Marble is not sustained by the weight of the evidence and was contrary to law.

That the granting of a new trial was clearly within my jurisdiction I have no doubt. The question I am to pass upon is whether this is a proper case for the exercise of that jurisdiction.

The learned counsel for Edison have called my attention to the practice in the English courts in the matter of granting new trials, and have suggested that the importance of the case and the possibility that another trial might result in a more satisfactory finding and decision should induce me to grant a rehearing.

I am aware that the practice in the English courts has been very liberal, but as has been remarked by an eminent judge in this country (Justice Story), such practice has resulted, in a great many cases, in vexatious delays and great hindrances in the administration of justice. The English practice has not been adopted nor does it obtain in this country.

Mr. Justice Story in the case of Jenkins *vs.* Eldridge (3 Story, 299), in commenting upon the principle that should govern the granting of rehearings referred to the English practice in the following language:

"I am aware of the English practice on this subject. It has guards which do not and cannot exist here where the counsel and the client are brought into immediate and constant contact with each other. But such as is the practice in England, it is a source of almost infinite delays and inconveniences; and under a chancellor like Lord Eldon, whose mental constitution led him to cherish interminable doubts, and to court rehearings, it must be a source of irreparable mischief and sometimes of unmitigated ruin. I have no desire to introduce such a practice into this court, when a
3608 cause has been once fully argued in this court, and an appeal lies from its decree there is, ordinarily, no reason for a rehearing here upon the original evidence; and if such a practice is to be introduced, it must be by the will and judgment of some one who shall succeed me. If rehearings are to be had until the counsel on both sides are entirely satisfied, I fear that suits would become immortal, and the decision be postponed indefinitely."

I do not overlook the fact that Justice Story in the remarks I have quoted, refers to a review on appeal as a means of correcting errors; but it must also be borne in mind that this case has been heard three times, and that the Commissioner himself sat as a court of review for the correction of errors. It does not appear that he failed to consider every legal proposition submitted or to consider fully all the evidence in the case. In fact, he seems to have gone over the whole case exhaustively. It is urged that he was aware of the fact that an appeal could be prosecuted from his decision to the Secretary of the Interior, and that in view of this he possibly gave the case less careful consideration than he otherwise would. I do not think this proposition sound. If an appeal was authorized, the influence upon the Commissioner would have been exactly the reverse from that which is suggested it could not, in the nature of things, have been otherwise. And beyond that I cannot deem it possible that an officer charged with the exercise of important judicial functions would neglect or be indifferent to the discharge of his duties because the result of such indifference might or could be corrected by a reviewing tribunal. Nor do I admit that I am, by law or sound precedent, required to grant a rehearing in thise case because I might reach a different conclusion from that of my predecessors. From the examination I have given the case I am not clear that I would reach the same conclusion he did; but that fact does not authorize, much less require, that I should set aside his decision unless I am at the same time convinced that the
3609 evidence does not warrant the finding made by him, and that the decision is in fact against the clear weight of the evidence.

To restate the legal proposition, before I can properly set aside a decision of a former Commissioner and retry the case, I must be satisfied that the decision was clearly against the weight of the evidence and against the law.

Hunt *v.* Smith, 3 Rich., Eq. 465.
Jenkins *v.* Eldridge, 3 Story, 299.
Adams Eq., p. 396, 398.
Everet *v.* Buffalo Oil Co., 22 Fed. Rep., 253.
Powell on Appellate Proceedings, 258.

If the mere fact that a court might not, or probably would not, have reached the same conclusion that a jury has, or that a judge hearing a motion for a new trial might have found differently from that of another who heard the cause, is to be regarded as ground for a new trial in every case, there would be no end to litigation, for it must occur that there is enough of doubt involved in many, not to say most cases, to render it uncertain what the finding of a jury will be, and to render it unsafe in the administration of public justice to disturb a finding merely because the judge hearing the motion might differ from the judge who rendered the decision as to the weight of the evidence. I am not prepared to say that the decision of Commissioner Marble is clearly against the weight of the evidence, or that his finding is not warranted.

While the rule laid down in Gill *vs.* Scott (29 O. G., 949), that (quoting from the syllabus) "after a case has been heard and decided by the Commissioner, it is competent for either party to move for a new trial or rehearing on the record. When, however, the party fails to make such motion, but prosecutes an appeal, the prosecution of such appeal operates as a substantial waiver of the right to subsequently make such motion" does not control my
3610 action in this behalf, I adhere to the principle there enunciated; but since there is no longer an appeal to the Secretary of the Interior that rule becomes unimportant.

It is urged by counsel for Edison that he is deprived of a right, since the appeal was taken away, and that as the finding of Commissioner Marble becomes practically final, the motion to set aside his decision should be granted.

I do not think the point well taken. This determination is not final so far as the rights of these contestants are concerned. The courts are open, and have a broader and fuller jurisdiction than I possess. If there is error in the decision of my predecessor which works a hardship upon either of the parties to this controversy, there is another forum where his action can be reviewed.

I am constrained on the whole case to dismiss the petition and overrule the motion.

BENJ. BUTTERWORTH,
Commissioner.

February 14, 1885.

(Endorsed: Sawyer & Man *vs.* Edison; Commissioner's decision; dated Feb. 14, 1885; recorded vol. 27, p. 337.)

3611 Duplicate.

Department of the Interior,
United States Patent Office,
Washington, D. C., *Feb.* 16, 1885.

In the Matter of the Interference of Sawyer and Man *vs.* Edison. } Motion for Rehearing.

Sir: You are hereby informed that the above motion has been overruled by the Commissioner and the petition dismissed.

By direction of the Commissioner.

Very respectfully, SCHUYLER DURYEE,
Chief Clerk.

Sawyer and Man, care Amos Broadnax, 10 Pine street, N. Y; T. A. Edison, care Geo. W. Dyer, present.

(Endorsement: Sawyer and Man *v.* Edison: notice of Commissioner's decision, Feb. 16, 1885.)

3612 No. 10 Pine Street, N. Y., 24 *February*, 1885.

Dear Sir: I this morning received the annexed notice and copy of petition, and I thereupon immediately served upon Mr. Edison's attorney the following notice of motion to dismiss the petition:

"Please take notice that on the record in this case, and all the papers and proceedings herein, I will move before the Commissioner of Patents on the 27th day of February, 1885, at 11 o'clock in the forenoon of that day, or as soon thereafter as counsel may be heard, that the petition filed by Thomas A. Edison and served upon me this 24th day of February, 1885, and which is set for hearing on the 2nd day of March, 1885, at 11 o'clock, a. m., be dismissed."

I trust your honor will find time to hear this motion to dismiss; your honor has now been all over this case, is familiar with it and can dispose of this matter with very little labor to yourself and to the parties. The petition is in substance a renewal of the motion for a rehearing.

Every point raised has been adjudicated by Commissioner Marble, and your honor has just denied a motion to rehear the case after a very full argument. The petition is vexatious, and is manifestly entered for delay merely; and it is thought that it ought to be disposed of by your honor before you leave the office, which I presume will not be later than the fourth of March. It is unjust that our application should be tied up by this kind of repeated motion after a full and fair hearing and after an exhaustive consideration and adjudication upon all the points raised by the motion or petition.

I have noticed the motion to dismiss for Friday, the 27th
3613 instant, fearing that your honor may leave the office before
the 2d of March, and I will be present then and ask your honor to hear the motion, a copy of which I enclose.

Very respectfully, AMOS BROADNAX.

To Hon. Com'r of Patents, Washington. D. C.

3614 U. S. Patent Office.

In Re Interference SAWYER AND MAN v. EDISON. } Paper Carbons.

To Amos Broadnax, Esq., attorney for Sawyer and Man:

Take notice that on the petition hereto annexed and on all the papers and proceedings herein we shall move before the Commissioner of Patents on the 2nd day of March, 1885, at 11 a. m. on that day for the relief prayed for in the first, second and third prayers of such petition.

RICHARD N. DYER,
Att'y for Edison.

3615 United States Patent Office.

In Re Interference SAWYER AND MAN *vs.* EDISON. } Paper Carbons.

The petition of Thomas A. Edison, by Richard N. Dyer, his attorney, respectfully shows:

First. That heretofore, and on the 11th of December, 1879, your petitioner filed an application for letters patent for improvement in electric light, and that subsequently an interference was declared between said application and a certain application filed by Sawyer and Man, for an improvement in electric lamps, the issue being stated to be in the language of the claim of your petitioner "the incandescent conductor for an electric lamp formed of carbonized paper."

That subsequently the parties to such interference filed their preliminary statements according to the practice in such cases, and that thereafter testimony was taken by the respective parties, and the matter coming up for argument before the examiner of interferences, priority of invention was awarded to Sawyer and Man; on appeal by your petitioner to the board of examiners-in-chief priority of invention was awarded to your petitioner; and on further appeal to the Commissioner of Patents priority of invention was awarded to Sawyer and Man; that an appeal was then taken by your petitioner to the Secretary of the Interior, and after argument, but before decision, was dismissed by reason of the decision of the Supreme Court of the United States in the case of Hoe *et al. v.* The Commissioner of Patents, holding that he had no jurisdiction 3616 in the premises, and that the practice theretofore existing in taking such appeal was unauthorized and contrary to law.

That your petitioner then moved for a rehearing of the case before the Commissioner of Patents, which motion was denied.

All of which appears by the record and papers on file in the Patent Office herein.

Second. That as your petitioner is informed and believes at the time the interference herein was declared it was the rule and practice in the Patent Office that an interference should be declared between applications setting forth explicitly or by inference the same invention, the whole application in each case being considered, irrespective of the fact whether there were conflicting claims; that there was no conflict in the claims of the parties hereto as appears by their respective applications on file in the office, but the interference was based on the assumption that they described the same or similar inventions.

That in the preliminary statement filed herein by Sawyer and Man they swore that they made the invention in interference as defined by the issue, and their preliminary statement taken in connection with their application made it necessary the interference should proceed, and it was so held by the office on motion to dissolve the interference made by them.

Third. That after the testimony of the parties hereto was taken, as your petitioner is informed and believes, it appeared by the testimony of Sawyer and Man that the invention set out in the issue herein was never made by them, and that the statement of facts in their said preliminary statement was not only not supported by, but was in fact contrary to the evidence.

3617 Fourth. That the application as originally made by said Sawyer and Man does not in fact disclose or claim the invention in interference, and their application and preliminary statement, as explained by their evidence herein, shows that such invention was never made by them.

Fifth. That at the several hearings had herein, it has been insisted by your petitioner that the application of Sawyer and Man, as explained by the evidence, did not in fact disclose the invention in issue, and that no interference in fact existed between the parties hereto. That Commissioner Marble, in his decision awarding priority of invention to Sawyer and Man, intimated that he did not consider that question properly before him, but that it was one that should be or should have been presented on a formal motion to dissolve the interference.

Sixth. That since the decision herein, the said Sawyer and Man have amended their application by inserting as a claim therein the issue in interference, which claim, as your petitioner is informed, is in no way supported by the application or the evidence, wherefore your petitioner prays:

1st. That the judgment heretofore made awarding priority of invention to Sawyer and Man be vacated and set aside, upon the ground that the inventions of the parties as fully disclosed by their testimony in said interference do not in fact interfere.

2nd. That letters patent be issued to your petitioner upon his application, and embodying the claim in issue in this interference.

3rd. And that your petitioner have such other and further relief as may be just and equitable in the premises

4th. And in the meantime, and until the hearing and decision on this petition, that all proceedings on the part of Sawyer and Man be stayed.

RICH'D N. DYER,
Att'y for Thos. A. Edison.

3618 STATE OF NEW YORK, } ss:
City and County of New York, }

Richard N. Dyer, being duly sworn, deposes and says: That he is attorney for Thomas A. Edison, petitioner above named; that he has read the foregoing petition, and that the same is true to his own knowledge, his knowledge being based upon the papers and records filed in the Patent Office herein; that the reason such petition is not verified by Thomas A. Edison is, that he is now absent from the city of New York, on his way to Florida.

RICHARD N. DYER.

Subscribed and sworn before me this 21st day of February, 1885.

[L. S.] JOHN C. TOMLINSON,

3622 United States Patent Office.

SAWYER AND MAN *vs.* EDISON. } Incandescent Conductors. Motion for Rehearing.

Application of Sawyer and Man filed Jan. 9, 1880.

Application of Edison filed Feb. 11, 1879.

Mr. Amos Broadnax for Sawyer and Man.
Messrs. J. C. Tomlinson and R. N. Dyer for Edison.

This motion for a rehearing on behalf of Edison, after reciting the leading facts in the proceeding heretofore had, including the fact that Mr. Commissioner Marble duly decided against the petitioner on the issue defined in the interference, and the fact that Mr. Commissioner Butterworth duly heard and denied a motion for a rehearing, proceeds to set forth the grounds why a rehearing should now be granted. These grounds are substantially as follows: That the interference was based on the assumption that the two applications described the same invention, whereas the original application of Sawyer and Man did not disclose the invention in interference, and the testimony taken shows that said invention was never made by Sawyer and Man, as has always been insisted upon by and on behalf of Edison—that is to say, rehearing is asked on the general allegations that there never has been an interference between the inventions of the parties, and that Edison has always said so, but has never been listened to.

I need scarcely remind counsel that since the entire pro-
3623 ceedings, from the declaration of interference to the present time, have been based on the judgment of the office that there was an interference, a general denial of the correctness of that judgment is not ground of reviewing one's own decision, much less the decision of a predecessor. I may also call attention to the remark of Mr. Justice Field, in Giant Powder Co. *vs.* Vigorit Powder Co. (5 Fed. Rep., 197), as follows:

A new hearing should not be had simply to allow a rehash of old arguments, which seems to be pertinent to this case. And I may conclude by quoting the closing paragraph of the decision, dismissing the former petition for rehearing, in which I concur.

The courts are open, and have a broader and fuller jurisdiction than I possess. If there is error in the de*de*cision of my predecessor, which works a hardship upon either of the parties to this controversy, there is another forum where his action can be reviewed.

There must be an end of litigation over a case in this office, and as I think that this case reached that end at date of the decision last mentioned, I must decline to reopen it. The motion for rehearing is therefore declined.

R. G. DYRENFORTH,
Acting Commissioner.

April 2, 1885.

Ex'd: A. H.

(Endorsement: Sawyer and Man *vs.* Edison; Commissioner's decision; dated April 2, 1885; recorded vol. 27, p. 460.)

3624 United States Patent Office.

THOMAS A. EDISON *vs.* SAWYER AND MAN. } Interference. Electric Lighting.

Upon motion to rehear.

Brief for Sawyer and Man.

This interference is between an application of Thomas A. Edison for a patent for "the incandescent conductor of an electric lamp formed of carbonized paper," filed December 11, 1879, and an application of Sawyer and Man for a similar invention filed January 9, 1880. Five years have elapsed since these applications were filed.

The interference was declared September 23, 1880.

On January 29, 1881, a motion was made on behalf of Sawyer and Man to dissolve the interference upon the ground that the claims did not interfere. This motion was opposed by Edison and denied by the examiner in charge of the case on January 28, 1881; and the decision of the examiner denying the motion was affirmed by the Commissioner, February 15, 1881.

The testimony was thereupon taken by the respective parties and the case duly submitted for hearing, and on January 20, 1882, the examiner of interferences rendered his decision, awarding priority of invention to Sawyer and Man.

A motion was thereupon made on behalf of Mr. Edison to vacate the decision and for leave to put in further testimony. This motion having been duly heard by the Commissioner, was granted July 24, 1882.

Mr. Edison thereupon put in all the testimony he had to offer and the case was again submitted for hearing and, on June 2, 1883, priority of invention was again awarded to Sawyer and Man.

3625 Thereupon the case was appealed to the board of examiners-in-chief and they awarded priority of invention to Edison.

Whereupon the case was brought before the Commissioner in person upon appeal and after an exhaustive argument on both sides, lasting fully twelve hours, he reversed the decision of the board and again awarded priority of invention to Sawyer and Man.

I have made the brief recital of the proceedings in this case to show your honor how very fully the case has been considered. Indeed upon an examination of the several briefs in the case on behalf of the respective parties I do not see how it is possible to suggest any point or aspect of the case that has not been fully presented and considered. Indeed, the decision of the Commissioner itself is an exhaustive consideration of the salient points in the case and cites fully and fairly the testimony upon which the decision is grounded.

But the decision, of course, did not suit the Edison Electric Light Company; and thereupon an appeal was taken to the Secretary of the Interior, an appeal that we move to dismiss upon the ground that the Secretary had no jurisdiction to entertain it.

That motion was of course denied. Having the utmost confidence in our case we went to a hearing before the Secretary, where the case was fully argued. In the meantime the mandamus proceedings in Gill *vs.* Scott was taken, which resulted in the Secretary dismissing this and all similar appeals for want of jurisdiction. And now, upwards of fifteen months after the decision of Commissioner Marble (rendered October 8, 1883,) we are met with a motion for your honor to rehear the case upon the record precisely as it stood when considered by your predecessor.

If the proponents had a case for rehearing why did they not take it before Commissioner Marble? Why did they take an appeal, when in law there was none, instead of moving for a rehearing, about the legality of which there was no doubt? The truth
3626 is, they had no case for a rehearing before Commissioner Marble, and much less have they any case before your honor. The moving papers do not make a case for rehearing not even before the Commissioner who decided the case, and certainly much less before his successor.

The "reasons of appeal" to the Secretary of the Interior make the ground upon which this motion is based. The appeal was taken for the reason that the Commissioner erred in law upon certain points, and erred in fact upon certain other points; and this motion is grounded upon a copy of such "reasons of appeal."

Errors in judgment about the points considered are always grounds for appeal, but never for rehearing; the latter is granted because some point of law or evidence has been overlooked, or not fully presented and considered. But where it appears that the law and evidence have been fully considered a rehearing is never granted because the counsel for the unsuccessful party is of the opinion that the court erred in its judgment upon the evidence, or upon the law.

The moving papers in this case are not supported by any affidavit whatever, and they do not allege that there was a single material point in the case, either of law or fact, that was not fully presented and considered by the Commissioner deciding it. On the contrary, the moving papers actually show that every material point in the case was considered by the Commissioner and decided by him. The motion is grounded upon the mere opinion of counsel that the Commissioner erred in his judgment upon the fact and law considered and decided by him. There is no other ground for this motion in the moving papers.

The language of Mr. Justice Coxe in denying a motion to rehear in the case of Everest *v.* Buffalo Lubricating Oil Company, decided November 29, 1884 (22 Fed. Rep. 253), is exactly pertinent here:

> "If it could be shown that the court had mistaken the
> 3627 facts, or manifestly misapprehended the law, it might be
> sufficient for a rehearing. But the fact that the defendant and his counsel think the decision erroneous is not enough, for it unfortunately seldom occurs that the court and the counsel for the unsuccessful party are in perfect accord in their view regarding the case. For errors in judgment ample remedy is provided by appeal."

The proponents elected to take an appeal to the Secretary and thereby waived their rights to move for a rehearing. In the recent case of Gill *vs.* Scott (29 C. Gaz., 949) your honor, reviewing facts precisely similar to those presented in this case, held:

> "By taking the appeal direct to the appellate tribunal the applicant waived his right to file a motion for a new trial. The fact that it was subsequently determined that the appellate tribunal had no jurisdiction to hear and determine the cause in my judgment made no difference; the right was substantially waived when the party declined to avail himself of it."

The proponents elected to take an appeal to the Secretary because they really had no grounds for rehearing before Commissioner Marble, as appears by their reasons of appeal upon which they base this motion; and if they had no grounds for rehearing before Commissioner Marble, how much worse are they off before his successor? For surely the Commissioner is bound by the rules of his own office. The only ground- upon which he can rehear this case are those upon which new trials are granted in the United States courts: not a single one of which is presented in these motion papers. (See Rules of Practice, § 139.)

The grounds upon which new trials are granted in the Federal courts, and rehearings by succeeding Commissioners in this office, *is* very fully stated in the following authorities:

Wait's Practice, III, p. 405, and cases cited.
Brown *vs.* Wilde, 12 Johnson, 455.
Dodd *vs.* Cobb, Com'r Decis., p. 196, of 1876.
3628 Blanchard *vs.* Jacobs, 2 Blatch., 71.
Rowe *vs.* Matthews, 18 Fed. Rep., 132.
Schneider *vs.* Thill, 3 Fed. Rep., 95.
U. S. *vs.* Millinger, 7 " " 187.
Robinson *vs.* Railroad, 9 " " 877.
Greenwalt *vs.* Tucker, 10 " " 884.
Dudley *vs.* Sears, 16 " " 335.
Josselyn *vs.* Swezey, Com'r Dec., p. 15, of 1879.
Huttner *vs.* Knox, " " 281, "
Giant Co. *vs.* Vigorit Co., Com'r, 5 Fed. Rep., 201.
Jarvis *vs.* Hathaway, 3 Johns., 180.
Marriot *vs.* Fearing, 11 Fed. Rep., 947.

In Wait's Practice (vol. III, p. 405) the law is thus summarized:

"Although there may be cases in which the ends of justice demand that the court should possess the power to correct abuses committed by a panel of jurors, that power should be limited by reasonable rule. It must be an abuse; it must be such a verdict as evinces that it was the result of passion, prejudice, mistake or corruption; such a verdict as shocks the common judgment; or such as is without evidence to support it, or is so against the striking preponderance of evidence that a common exercise of judgment demands its reversal. * * * And the findings of fact by a referee, where there is a conflict of evidence, is as conclusive as the verdict of a jury."

In Blanchard's Gun Stock Turning Factory *vs.* Laban Jacobs (2 Blatch., 711) Judge Betts said (case of infringement of letters patent):

"The rule laid down in Ward *vs.* Centre (3 Johns., 572) that the verdict of a jury will not be set aside where there has been evidence on both sides of a question of fraud, and no misdirection as to law, is applied with like strictness in all cases of tort." (Jarvis *vs.* Hatheway, 3 Johns., 180.)

3629 In the late case of Rowe *vs.* Matthews (18 Fed. Rep., 133), decided Oct. 15, 1883, Judge Brown said:

"In their numerous exceptions counsel for defendants seem to have shared in a misapprehension which, judging from the number of motions of this character is a common one, that nothing more is necessary to entitle a party to a new trial than to show such errors as would be deemed sufficient by an appellate court to justify setting aside the verdict. Nothing could be more misleading than this idea. * * * Errors in the admission of testimony or in the instructions of the court, even though material, do not, as matter of law, necessitate a reversal of the proceedings. * * * Nothing is better calculated to demoralize the administration of justice, and to justify the popular belief in the uncertainty of the law, than the practice of granting new trials upon trivial grounds to give the defeated party another chance"

In denying a motion for rehearing in Marriot *vs.* Fearing (11 Fed. Rep., 846) Judge Wheeler said:

"There is nothing to indicate that the jury were actuated by either passion or prejudice. To grant a new trial would be merely to allow an appeal upon these questions of fact from that jury to another. That is not allowable by the rules of law or the practice of courts."

In Huttner *vs.* Knox (Com'r Decis., p. 281 of 1879) Com'r Paine held that, "a decision of a Commissioner rejecting a claim for want of patentability, on motion to dissolve an interference, cannot be reopened by his successor in office, under rule 45 (now 139) except in accordance with the principles which govern new trials; that a decision was against the evidence adduced on the hearing can only be asserted, as a valid ground for a rehearing, when either there was no evidence at all to support the decision, or the preponderance of evidence against it was clear and decided.

Giant Powder Co. *vs.* California Viogrit Powder Co. 5 Fed. Rep., 201.

3630 Mr. Justice Field said:

"A rehearing should not be granted for newly discovered evidence where the evidence could have been obtained by reasonable diligence on the first hearing, nor when it is merely cumulative to that previously received, nor when, if presented, it would not have changed the result. And as to errors of law they should be such as are clearly shown by considerations not previously presented. A new hearing should not be had simply to allow a rehash of old arguments. The proper remedy for errors of the court on points argued in the first hearing is to be sought by appeal, when the decree is one which can be received by an appellate tribunal. (See Tufts *vs.* Tufts, 3 M. and W., 426.) * * *

"Before concluding it may not be amiss to invite the attention of complainant's counsel to the language of Judge Story in the case of Jenkins *vs.* Eldridge, with respect to the earnestness with which counsel, in applying for rehearings, sometimes asseverate their convictions to the errors of the court; and to repeat what is there said: 'That if any judge should be so unstable in his views or so feeble in his judgment, as to yield to them, he would not only surrender his independence but betray his duty. However humble may be his own talents, he is compelled to treat every opinion of counsel, however exalted, which is not founded in the law and the facts of the case, as voiceless and valueless.' (3 Story, 303.) Nothing can be gained by the strong language expressed by counsel in presenting the petition as to the supposed errors of the court nor by the statements as to what may have been said of the decision by other counsel who have neither examined, studied, nor understood the case."

(Endorsement: United States Patent Office; Edison *vs.* Sawyer and Man; interference, electric lighting; motion to rehear; brief on behalf of Sawyer and Man; Broadnax and Bull, 10 Pine street, N. Y.)

Title: Improvement in —.

3633 In the United States Patent Office.

Application of WILLIAM E. SAWYER and ALBON MAN for a Patent for Improvement in Electric Lamps. Filed Jan. 9th, 1880. No. 547.

The fourth claim of this application having been in interference with an application of Thomas A. Edison for a patent for a similar invention, filed Dec. 11, 1879, case 187, and priority of invention having been finally awarded to Sawyer and Man, the appeal to the Secretary of the Interior having been dismissed for want of jurisdiction, the application is now presented for the further action of the office, and to that end the specification is hereby amended by adding to the claims now pending the following claim:

3.
A.
Erased Feb. 28, '85.

5th. The incandescent conductor for an electric lamp, formed of carbonized paper, substantially as set forth.

The foregoing claim being the single claim of the application of Edison, the office having made that claim the subject-matter of the interference aforesaid.

The 1st, 2d and 3d amended claims, filed May 17, 1880, on behalf of Sawyer and Man having been but once rejected by the primary examiner are now respectfully submitted for reconsideration—the undersigned being of the opinion that the reference cited does not anticipate the claim.

Respectfully submitted.

AMOS BROADNAX.

Dec. 4th, 1884.

(Endorsed: U. S. Patent Office, Dec. 4, 1884; division XVI; serial No. 547; paper No. 8; am'd't A; filed Dec. 4, 1884.)

3634 Serial No., 547.

Room 91.

DEPARTMENT OF THE INTERIOR,
UNITED STATES PATENT OFFICE,
WASHINGTON, D. C., *Feb.* 19, 1885.

Application, "electric lamps or lights." Filed Jan. 9, 1880.

William E. Sawyer and Albon Man, care Amos Broadnax, 57 Broadway, New York city:

The interference with Edison having been decided in favor of applicants, this case has been reconsidered as requested by letter accompanying the amendment filed Dec. 4, 1884.

It appears that in the specification there are two terms used in a manner that renders it somewhat difficult to understand what ap-

---

[Matter enclosed between rules erased in copy.]

plicants desire to express by the same; these terms are "arc" and "arch." The first seems to be intended as designating the light-giving portion of the lamp, irrespective of its form, and the second seems to be a generic description of the form of the light-giving portion of the lamp. While this is the probable intended meaning of these terms it is clear that the term "arc" is not a proper designation of the light-giving portion, and its use is calculated to confuse the reader; it is unquestionably a source of obscurity and ambiguity which should be removed by proper amendment. The number of the patent granted to applicants June 18, 1878, to which reference is made in the specification, is No. 205,144, and not 206,144 as given in the specification; this should be corrected. The word "cylindrical," on p. 2, line 15, should be changed to circular.

Claims 2 *x* 3 are held to be fully anticipated by English patent No. 3809 of 1872, Fig. 8.

C. J. KINTNER, *Examiner.*

JOS. LYON, 1*st Ass't.*

(Endorsed: Serial No. 547; paper No. 9; rej.; dated Feb. 19, 1885.)

3635 In the United States Patent Office.

Application of WILLIAM E. SAWYER and ALBON MAN for a Patent for Improvement in Electric Lamps. Filed January 9th, 1880. Serial No., 547.

Amend the substituted specification filed May 17th, 1880, as follows:

In line 18, page 1, strike out the figures 206,144 and in lieu thereof substitute the figures 205,144.

In line 15, page 2, strike out the word "cylindrical" and substitute the word "circular."

In line 2, from the bottom of page 1, strike out the word "arc" and substitute the word "arch."

In line 14, page 2, strike out the word "arc" and substitute the word conductor. In line 15, same page, strike out the word "preferably" and substitute the word made.

In line 18, page 2, strike out all after the word paper; and in line 19, same page, strike out all before the word "we" and in lieu thereof substitute the following: also wood, carbon, charcoal and the like.

In the first line of the first claim strike out the word "arc" and substitute the word conductor.

Strike out the 2 and 3 claims.

Respectfully submitted.

AMOS BROADNAX, *Att'y.*

Dated Feb. 19th, 1885.

(Endorsed: Serial No., 547; paper No. 10; U. S. Patent Office, Feb. 19, '85; am'd't filed Feb. 19, 1885; division XVII.)

3636 In the United States Patent Office.

Application of WILLIAM EDWARD SAWYER and ALBON MAN for a Patent for Improved Electric Lamps. Filed January 9, 1880. Serial No., 547.

The above-entitled application is hereby further amended as follows:

In line 20, page 2, strike out the word "arcs" and insert the words incandescing conductors.

In line 23, same page, strike out the word "arcs" and insert the words incandescing conductors.

Respectfully submitted.

AMOS BROADNAX, *Att'y.*

Dated Feb. 20, 1885.

(Endorsement: Serial No. 547; paper No. 11; am'd't. Filed Feb. 20, 1885. U. S. Patent Office, Feb. 20, 1885; division XVI.)

3637 Serial No., 547.

(Room 91.)

DEPARTMENT OF THE INTERIOR,
UNITED STATES PATENT OFFICE,
WASHINGTON, D. C., *Feb.* 20, 1885.

Application, electric lamps or lights. Filed Jan. 9, 1880.

William E. Sawyer and Albon Man, care Amos Broadnax, 57 Broadway, N. Y. city:

By the amendments filed Feb. 19, and Feb. 20, 1885, the objections heretofore urged have been removed, and as at present advised the case is now ready for issue; final action, however, must be suspended until March 2, 1885, in view of a possible interference with another pending application.

C. J. KINTNER, *Ex.*

JOS. LYONS, 1*st Ass't.*

(Endorsement: Serial No. 547; paper No. 12; letter dated February 20, 1885.)

3638 In the United States Patent Office.

In the Matter of the Application of SAWYER AND MAN for Electric Lamps. Filed Jan'y 9, 1880. } No. 547.

To the examiner in charge:

Your honor will find annexed an amendment in this case. My reasons for filing this amendment are, that the specification, as it now stands, is defective in not clearly pointing out the objects of the improvements described and the various modes of carrying them into effect.

It is for the purpose of making the specification more definite that this amendment has been prepared, and is now filed.

Respectfully, AMOS BROADNAX,
Attorney for Sawyer & Man.

Washington, D. C., February 28th, 1885.

3639 In the United States Patent Office.

In the Matter of the Application of SAWYER AND MAN for Electric Lamps. Filed Jan'y 9, 1880. } No. 547.

Amendment.

Amend the specification herein by erasing all after the words "granted to us June 18, 1878."

Last words of paragraph 2, page 1, down to the signatures of inventors and witnesses, and substitute in lieu thereof the following:

B. Our invention relates more especially to the incandescing conductor, its substance, its form and its combination with the other elements composing the lamp. Its object is to secure a cheap and effective apparatus and our improvement consists, first, of the combination in a lamp chamber, composed wholly of glass, as described in patent No. 205,144, of an incandescing conductor of carbon

---

having the form of an arch or loop in the circuit, as the light-giv*en* medium, and also of an incandescing conductor composed of carbon made from a vegetable fibrous material in contradis-tion to a similar conductor made from mineral or gas carbon.

Substitute C, March 13, '85.

The accompanying drawings show all our improvements embodied in an apparatus or lamp, substantially like that represented in the patent above referred to, being the form in which we have practically used it, but some of our improvements may be used in connection with other forms of lamps with equally good effect.

Reference being had to said drawings:

Fig. 1 is a top view of the lamp.

Fig. 2 a side elevation thereof.

Fig. 3 a side view in elevation of the burner on an en-
3640 larged scale to show its details more clearly; and

Fig. 4 is a similar edge view.

[Matter enclosed between rules erased in copy.]

Substitute D, March 13, '85.

The lamp or apparatus embracing our improvements being constructed substantially as that described and illustrated in the patent above mentioned and constituting no part of the subject-matter hereinafter claimed, excepting as hereinafter stated, needs no particular description beyond what is necessary to point out the features of novelty constituting the improvements covered by the claims.

March 13, '85.
March 14, '85.

In the practice of our invention we have made use of carbonized paper and also wood carbon, [charcoal, and ordinary gas carbon.]* We have also used such conductors or burners of various shapes, such as pieces with their lower ends secured to their respective supports and having their upper ends united so as to form an inverted-Λ-shaped burner. We have also used conductors of varying contours, that is, with rectangular bends instead of curvilinear ones, but we prefer the arch shape.

Insert F, April 21, '85.
Erased March 14, '85.

In making these carbons from the fibrous material, our practice has been to cut the burner to the desired form before carbonization, and this we found to be much the best practice, although it is possible in some forms of burners made from paper or other sheets of fibrous material, to cut or form the burner after carbonization.

An important practical advantage which is secured by the arch form of incandescing carbon is that it permits the carbon to expand and contract under the varying temperature to which it is subjected, when the electric current is turned on or off, without altering the position of its fixed terminals. Thus the necessity for a special mechanical device to compensate for the expansion and contraction which has heretofore been necessary, is entirely dispensed with, and thus the lamp is materially simplified in its construction. Another advantage of the arch form is that the shadow cast by such burners is less than that produced by other forms of burners when fitted with the necessary devices to support them.

3641 & 3642

Another important advantage resulting from our construction of the lamp results from the fact that the wall forming the chamber of the lamp, through which the electrodes pass to the interior of

---

[* Words enclosed in brackets erased in copy.]
[Matter enclosed between rules erased in copy.]

the lamp, is made wholly of glass, by which all danger of oxidation, leakage or short circuiting is avoided.

The advantages resulting from the manufacture of the carbon from vegetable, fibrous or textile material instead of mineral or gas carbon, are many; among them may be mentioned the convenience afforded for cutting and making the conductor in the desired form and size, the purity and quality of the carbon obtained, its susceptibility to tempering, both as to hardness and resistance, and its toughness and durability.

We have used such burners in closed or hermetically sealed transparent chambers, in a vacuum, in nitrogen gas, and in hydrogen gas; but we have obtained the best results in a vacuum, or an attenuated atmosphere of nitrogen gas, the great desideratum being to exclude oxygen or other gases capable of combining with carbon at high temperatures from the incandescing chamber, as is well understood.

The nature of our inventions and the operation of our improved lamp will be readily understood from the foregoing description and the following claims:

We claim as our joint invention:

I. An incandescing conductor for an electric lamp of carbonized fibrous or textile material, and of an arch or horseshoe shape, substantially as hereinbefore set forth.

II. The combination substantially as hereinbefore set forth, of
an electric circuit, and an incandescing conductor [arch]*
April 21, '85. of carbonized fibrous material included in, and
3643 forming part of said circuit, and a transparent
April 21, '85. hermetically sealed chamber, in which the conductor [arch]*
is enclosed.

III. The incandescing conductor for an electric lamp formed of carbonized paper substantially as described.

IV. An incandescing electric lamp consisting of the following elements in combination: First, an illuminating chamber made wholly of glass hermetically sealed and out of which all carbon-consuming gas has been exhausted or driven; second, an electric circuit conductor passing through the glass wall of said chamber
3, 13, '85. and hermetically sealed therein ‸ as described; third, an illu-
minating conductor in said circuit and forming
April 21, '85. part thereof within said chamber, consisting of
3, 13, '85. carbon ‸ made from a fibrous or textile material having the form of an arch or loop, sub-
stantially as described for the purpose specified.

Respectfully submitted.

AMOS BROADNAX,
Attorney for Sawyer and Man.

Washington, D. C., February 28th, 1885.

[* Words enclosed in brackets erased in copy.]

(Endorsement: Serial No. 547; paper No. 13; am'd't B; filed Feb'y 28, 1885; U. S. Patent Office, Feb'y 28, 1885; div. XVI.)

3644 Serial No., 547.

Room 91.

Department of the Interior,
United States Patent Office,
Washington, D. C., *March* 7, 1885.

Application, electric lamps or lights. Filed January 9, 1880.

William E. Sawyer and Albon Man, care Amos Broadnax, 57 Broadway, N. Y. city:

This case has been reconsidered with reference to the new specification filed February 28, 1885.

The new statement of invention which precedes the description, and which substantially agrees with the present fourth claim, is objectionable for the reason that said claim cannot be allowed in view of the prior state of the art. Arch-shaped pieces of carbon, as incandescent elements in electric lamps, are old, as shown in English patent, No. 3809, of 1872 (Fig. 8), and a lamp chamber composed wholly of glass and constructed in exactly *in* the manner described in claim 4 is old with applicants, as shown by their patent No. 205,144, June 18, 1878. The use of an old carbon arch in an old electric light chamber is not an invention. It is clear that the only invention presented in this case is the incandescing conductor made of carbonized paper, and the claims as well as the statement of invention should be strictly confined to this element and to novel combinations of the same with other elements. When such claims are presented no objection will be made to the use of generic terms since in the application as originally filed the incandescing conductor was described in the fourth claim, as made of "carbonized fibrous or textile material." Nor will objection be made to a more extended or more specific description of the manner of making and constructing the lamp shown, but in a case like 3645 this, where the art of electric lighting has greatly developed since the filing of this application, the limits of the invention to which applicants are entitled should be well defined by general and specific disclaimers of everything beyond the arch or carbonized paper, and the new combinations of the same with other elements.

Additional description is indeed desirable, but it should be based upon additional drawings made from the model filed in this case, and said model should be identified in a manner that will admit of no doubt.

Claim 4 stands rejected.

C. J. KINTNER, *Ex.*

JOS. LYONS, 1*st Ass't.*

(Endorsed: Serial No. 547; paper No. 14; rej.; dated Mar. 7, 1885.)

3646 In the United States Patent Office.

In the Matter of the Application of SAWYER AND MAN for Electric Lamps. Filed January 9, 1880. } No. 547.

Amendment.

In response to office letter of the 7th instant, this application is further amended by striking out all after the word "carbon" in line 7 of the statement of invention, page 1 of the amended specification, filed February 28, 1885, and by substituting in lieu thereof the following:

C. Made from a vegetable fibrous material in contradistinction to a similar conductor made from mineral or gas carbon, and also in the form of such conductor, so made from such vegetable carbon, and combined in the lighting circuit within the exhausted chamber of the lamp.

Amend also by striking out lines 5 to 11 inclusive, page 2 of said specification, and substitute the following:

D. Fig. 5 of the drawing shows a vertical section through the bottom of the lamp; in this figure *x* is a glass flange on the bottom of the lamp chamber, *y*, is a glass disk corresponding in size to the flange and is ground to the bottom thereof to form an air-tight joint, so that the entire wall of the chamber is formed of glass; the electrodes passing through the glass disk in the manner shown, to form the lighting circuit in the chamber; substantially as in said patent No. 205,144; the sealing of the electrodes, where they pass through the glass wall, is done with any suitable cement, or in any of the 3647 well-known methods of sealing glass upon metal electrodes previous to the filing of this application.

The electric connections of this lamp are made in the base thereof, substantially the same as in our patent No. 210,809, dated December 10, 1878, and the whole bottom is enclosed in a cup filled with wax or other suitable cement the same as in that patent. The cement sealing in this lamp being also applied in substantially the same way as in the patent last above mentioned.

Insert E, April 21, '85. }

3, 14, '85. And further amend by striking out the words "charcoal and ordinary gas carbon," in lines 13 and 14, page 3 of said specification, and in lieu thereof insert the words ["of different kinds."]*

Amend the 4th claim by inserting in line 8, after the word "carbon" the following: "Made from a vegetable fibrous or textile material."

[* Words enclosed in brackets erased in copy.]

And further amend said claim by inserting the words "as described" in line 6, after the word "therein."

The application is also amended by filing the additional drawing, Fig. 5, as suggested by the examiner's letter above mentioned.

Respectfully submitted.

AMOS BROADNAX,
Attorney for Sawyer and Man.

Washington, D. C., March 13, 1885.

(Endorsement: Serial No. 547, paper No. 15. *Adm*'t- C, D, filed March 13, 1885, United States Patent Office, March 13, 1885; division XVI.)

3649 (Interferences.)

Room No. —.

DEPARTMENT OF THE INTERIOR,
UNITED STATES PATENT OFFICE,
WASHINGTON, D. C., *March* 14, 1881.

William E. Sawyer and Man, assignors to Electro-Dynamic Light Co., N. Y. city, care Amos Broadnax, 57 Broadway, N. Y. city:

Please find below a copy of a communication from the examiner concerning your application for a patent for improvement in electric lamps, No. 517, filed Jan. 9, 1880.

Very respectfully, R. G. DYRENFORTH,
Act'g Commissioner of Patents.

3650 Room No. 91.

Your case above referred to is adjudged to interfere with others hereafter specified, and the question of priority will be determined in conformity with the rules.

The statement demanded by rule 105 must be sealed up and filed on or before the — day of ——, 188–, with the subject of the invention and name of party filing it indorsed on the envelope. The subject-matter involved in the interference is, first, an incandescent electric lamp, consisting of an enclosing globe or receiver and a conducting strip, ribbon, or loop of carbonized paper attached to metallic conductors passing into the said receiver. Freeman's first claim in substance the same as applicant's second and fourth claims.

2nd. As an incandescent medium for electric lamps a strip, ribbon or filament of carbonized paper, Freeman's second claim in substance; applicant's first and third claims.

The opposing party to this interference is Walter K. Freeman of Brooklyn, Kings Co., N. Y., assignor to Chas. R. Flint of New York.

Freeman's attorneys of record are Parker W. Page of New York city, and Marcellus Bailey, of Washington, D. C.

C. J. KINTNER, *Ex'r.*

(Endorsement: Serial No. 547; paper No. 17; intf. with Freeman; dated M'ch 14, 1884.)

3651 In the United States Patent Office.

Application of SAWYER AND MAN for a Patent for Improved Electric Lamps. Filed January 9, 1880. No. 547.

Amendments.

This specification is further amended by adding after the word "mentioned," in line 7, page 2, of amendment filed March 13, 1885, the following:

> E. The invention making the subject-matter of this application being improvements upon the lamps described in the patents above referred to, to the extent of the claims making part hereof.

Amend further by inserting the following paragraph after the word "shape," in line 20, page $\overset{2}{[3]}$* of amendment filed February 28, 1885:

> No especial description of making the illuminating-carbon conductors described in this specification and making the subject-matter of this improvement, is thought necessary, as any of the ordinary methods of forming the material to

---

[* Figure enclosed in brackets erased in copy.]

F. be carbonized to the desired shape and size, and carbonizing it while confined in retorts in powdered carbon substantially according to the method in practice before the date of this improvement may be adopted in the practice thereof, by any one skilled in the arts appertaining to the making of carbons for electric lighting or for other use in the arts.

3652 Amend further by striking out the word "arch," in lines 2 and $\overset{5}{[4,]}$* claim 2, and substitute therefor the word conductor.

Amend further by striking out the word "veg*i*table," in line 8, claim 4.

Respectfully submitted.

AMOS BROADNAX,
Att'y for Sawyer and Man.

Dated April 21st, 1885.

(Endorsed: Serial No. 547; am'd't- E, F; 19. Filed Ap'l 21, 1885. U. S. Patent Office, April 21, 1885. Division XVI.)

3653 U. S. PATENT OFFICE,
WASHINGTON, D. C., *Apr.* 22, 1885.

Wm. E. Sawyer and A. Man, care of Amos Broadnax, No. 57 Broadway, N. Y. C.

SIR: Your application for a patent for an improvement in electric lights, filed Jan. 9, 1880, has been examined and allowed.

The final fee, twenty dollars, must be paid, and the letters patent bear date as of a day not later than six months from the time of this present notice of allowance.

If the final fee is not paid within that period the patent will be withheld, and your only relief will be by a renewal of the application, with additional fees, under the provisions of section 4897, Revised Statutes. The office aims to deliver patents upon the day of their date, and on which their term begins to run; but to do this properly applicants will be expected to pay their final fees at least twenty days prior to the conclusion of the six months allowed them by law. The printing, photo-lithographing and engrossing of the several patent parts, preparatory to final signing and sealing, will consume the intervening time, and such work will not be done until after payment of the necessary fees.

When you send the final fee you will also send, distinctly and plainly written, the name of the inventor and title of invention as above given, date of allowance (which is the date of this circular), date of filing, and, if assigned, the name of the assignees.

If you desire to have the patent issue to assignees, an assignment containing a request to that effect, together with the fee 3654 for recording the same, must be filed in this office on or before the date of payment of final fee.

[* Figure enclosed in brackets erased in copy.]

Additional copies of specifications and drawings will be charged for at the following rates: Single copies, uncertified, 25 cents; twenty copies or more, 10 cents each. The money should accompany the order.

Very respectfully, M. V. MONTGOMERY,
Commissioner of Patents.

Title: Improvement in electric lights.
Ex'd: E. L. L. 36 Electricity.
C. F. Electric lights.

3659 EXHIBIT 13.

Received for record Oct. 22, 1878, and recorded in Liber H 23, page 448 of Transfers of Patents.

[SEAL.] In testimony whereof I have caused the seal of the Patent Office to be hereunto affixed.

W. H. DOOLITTLE,
Acting Commissioner.

Whereas, we, William Edward Sawyer, of the city, county and State of New York, and Albon Man, of Brooklyn, county of Kings, and State aforesaid, have made the following-entitled inventions, viz:

Firstly. Certain improvements in "electrical lighting apparatus and circuits."

Secondly. Certain improvements in "carbons for electric lights" and in the treatment thereof—for which we are about to apply for letters patent of the United States; and whereas the "Electro-Dynamic Light Company," a corporation created and existing under and by virtue of the laws of the State of New York, has purchased of us all our right, title and interest in and to said inventions and any and all letters patent of the United States, which may be hereafter granted for the same, and has paid us for the said inventions the sum of one dollar and given us other good and sufficient consideration for the same, the receipt of which we hereby acknowledge and with which we hereby declare ourselves satisfied, contented and paid, now, therefore, upon consideration aforesaid, we, the said William Edward Sawyer and Albon Man, have and do hereby sell, assign and convey to the said company the whole of our right, title and interest in and to said inventions, and any and all United States letters patents which may hereafter be granted 3660 for the same, for the said company to have, hold and enjoy for its own use and behoof and for the use and behoof of its legal representatives as fully and entirely as we would have held and enjoyed the same had this assignment and sale not been made, for the whole term for which said letters patent may be granted, including any extensions thereof, and through the whole of the United States and the territories thereof; and we do hereby covenant, for ourselves and our legal representatives, that we are now the sole owners of *of* said inventions and have good right and lawful authority to make and execute this conveyance, in manner aforesaid, and that we will at any and all proper and reasonable times make and execute any and all proper papers that may be necessary to apply for and obtain letters patent of the United States, for said inventions, and any and all proper papers that may be necessary to vest the title thereof in said corporation.

In witness whereof we hereunto set our hands and seals this, the 14th day of October, 1887.

W. E. SAWYER. [SEAL.]
ALBON MAN. [SEAL.]

Witnesses:
WILLIAM H. BROADNAX.
AMOS BROADNAX.

Endorsement: Consol. E. L. Co.; G. 3,553.

3661 EXHIBIT 14.

In consideration of the sum of five dollars to us in hand paid, we hereby assign, sell, and set over to the Electro-Dynamic Light Company of New York, our entire right, title and interest in and to an improvement in electric lights, as set forth in an application this day prepared and executed by us preparatory to applying for letters patent therefor; and we hereby request the Commissioner of

Patents to issue the said patent to the aforesaid company as our assignee.

Dated January 8, 1880.

WILLIAM EDWARD SAWYER.
ALBON MAN.

Witnesses:
WM. D. BALDWIN.
WM. H. CHURCH.

(Endorsed: Ex'd. F. C. T. U. — Patent Office. Received for record Jan. 9, 1880. Recorded Liber W 24, page 380. Consol. E. L. Co. *vs.* Edison E. L. Co. Compl't's Ex't No. 14. Assignment of Sawyer and Man to E. D. L. Co., May 11, 1886, T. G., exam.)

3662 EXHIBIT 15.

Received for record Oct. 5, 1882, and recorded in Liber J 28, page 429 of Transfers of Patents.

[SEAL.] In testimony whereof I have caused the seal of the Patent Office to be hereunto affixed.

Ex'd: M. T.

E. M. MARBLE,
Commissioner.

This deed of assignment, made this, the sixth day of April, 1881, between the Electro-Dynamic Light Company, a corporation created and existing under, and by virtue of the laws of the State of New York, of the first part; and William H. Church, of Brooklyn, county of Kings and State of New York, of the second part;

Witnesseth: That for the consideration hereinafter mentioned, the said Electro-Dynamic Light Company has and does hereby assign, transfer and convey to the said William H. Church, all and singular the letters patents of the United States, dated and numbered as follows, viz: one dated June 25, 1878, and numbered 205,303 for "improvement in electric lighting systems;" one dated June 18, 1878, and numbered 205,144 for "improvement in electric lamps;" one dated June 25, 1878, and numbered 205,305, for "improvements in regulators for electric lights;" one dated November 19, 1878, and numbered 210,152, for "improvement in switches for electric lights;" one dated December 10, 1878, and numbered 210,809, for "improvements in electric lamps;" one dated January 7, 1879, and numbered 211,262, for "improvements in carbons for electric lights;" one dated June 29, 1880, and numbered 229,335, for "carbons for electric lights;" one dated June 29, 1880, and numbered 229,476, for "improvement in electric switches;" one dated November 19, 1878, and numbered 210,151, for "improvement 3663 in electric meters;" one dated September 16, 1879, and numbered 219,771, for "improvement in electric lamps;" one dated February 8, 1881, and numbered 237,632 for "dynamo-electric machines;" and also two undivided fifths of the whole of letters patent of the United States, numbered and dated as follows, viz: one dated August 14, 1877, and numbered 194,111 for "electric engineering and lighting apparatus and system;" one dated August 21, 1877, and numbered 194,500, for "electric candles;" one dated August 28, 1877, and numbered 194,563, for "electric lighting apparatus;" one dated November 6, 1877, and numbered 196,834, for "electric engineering and lighting systems;" which interests in said last-mentioned letters patent were assigned by William E. Sawyer to Albon Man by a certain deed of assignment dated May 14, 1878, and recorded in Liber S 22, page 464, Transfers of Patents, and which interest- in said patents were duly assigned by said Albon Man to said Electro-Dynamic Light Company by deed of assignment duly recorded in the Patent Office in Liber C 24, *in* pages 294, 295, 296 and 297 and dated all of them July 15, 1878; together with all and singular the inventions owned by said company, and described, illustrated, claimed or suggested in said letters patents, and also all inventions owned by said company for which applications for patents are now pending in the United States.

And also covenants, assignments and agreements made by William E. Sawyer with Albon Man and assigned to said Electro-Dynamic Light Company and which are now owned by said company having reference to said patents and inventions, any or either of them, in which said company is interested, in so far as the said covenants or agreements appertain to letters patents for said inventions, any or either of them, in the United States of America, but not elsewhere; for the said William H. Church to have, hold and enjoy for his own use, benefit and behoof, and for the use, benefit 3664 and behoof of his assigns and legal representatives to the full end of the term for which said letters patent have been, or may hereafter be granted, issued, reissued or extended, any or either of them, in and for the whole of the United States and the territories, thereof, and also all covenants and agreements at any time made by the said William E. Sawyer and Albon Man, or either of them, jointly or severally, with the said Electro-Dynamic Light Company for the reissue or extension of said letters patent, any or either of them, or that in anywise appertains to said patents and inventions or applications for patents for the same in the United States of America, but not elsewhere; and that as fully and entirely as the same would, might or could have been held and enjoyed by the said Electro-Dynamic Light Company had this assignment and transfer not been made.

In trust, nevertheless, for the said William H. Church to hold to the use and benefit of the said Electro-Dynamic Light Company and especially to assign, transfer and convey to the Eastern Electric Manufacturing Company of Middletown, Connecticut.

All and singular the said letters patents and inventions and applications for letters patents, and the covenants and agreements aforesaid, the same to all intents and purposes as the said Electro-Dynamic Light Company does hereby assign, transfer and convey the said letters patents inventions, applications for patents, covenants and agreements to the said William H. Church and his assigns.

The consideration for this deed is that the said William H. Church subscribe for nine-twentieths of the whole of the capital stock of the Eastern Electric Manufacturing Company, and pay for the same by transferring, conveying and assigning to said company the whole of said letters patents, inventions, applications for letters patents, covenants and agreements aforesaid. The said William H. Church being hereby authorized to receive from said company the certificate or certificates of transfer of said stock of said Eastern Electric Manufacturing Company, and hold the same for the use and benefit of the share and script holders of the Electro-Dynamic Light Company and to thereupon divide the same among said share and script holders of the Electro-Dynamic Light Company according to their respective interest in said company, after having first assigned and transferred to such persons as shall be designated by the trustees of the Electro-Dynamic Light Company such shares of stock of the Eastern Electric Manufacturing Company as the said board of trustees deem expedient and proper, and which division of shares having been made and accepted as aforesaid, the trust hereby created shall cease and determine and the said trustee shall be discharged of his said trust. 3665

It being the intention of this instrument that the said William H. Church as such trustee shall convey to the said Eastern Electric Manufacturing Company the title absolutely to the letters patents, inventions, applications for letters patents, covenants and agreements aforesaid, and not to continue the trust hereby created.

In witness whereof the said Electro-Dynamic Light Company has hereto subscribed its name and affixed its seal by its president and treasurer the day and year above written.

ELECTRO-DYNAMIC LIGHT COMPANY,
By THO. WALLACE, *President.*
JACOB HAYS, *Treasurer.*

Witness:
AMOS BROADNAX.

3666 CITY, COUNTY, AND STATE OF NEW YORK, *ss:*

On this, the 15th day of December, A. D. 1885, personally came before me Jacob Hays, to me personally known to be the person whose name is hereto subscribed, and made solemn oath that on the sixth day of April, 1881, on the day of the date of the execution of the within assignment, he was treasurer of the Electro-Dynamic Light Company, and that Thomas Wallace was president of said company, at the date last aforesaid; and that the said instrument was signed by the said Thomas Wallace as president of said compa*d*y, and by deponent as treasurer thereof; and that the signatures written at the foot of said assignment are the signatures of deponent and said Thomas Wallace; and that they were duly authorized by said company to execute said instrument in manner and form as aforesaid.

JACOB HAYS.

Subscribed and sworn to before me this 15th day of December, 1885.

In testimony whereof I have caused the seal of the Patent [L. S.] Office to be hereunto affixed.

E. M. MARBLE,
Commissioner.

Ex'd: M. T.

This deed of assignment, made this the sixth day of April, 1881, between William H. Church, of Brooklyn, in the county of Kings and State of New York, trustee of the Electro-Dynamic Light Company, and of its share and scrip holders, of the first part; and the Eastern Electric Manufacturing Company of Middletown, Connecticut, a corporation created and existing under and by virtue of the laws of the State of Connecticut, and having an office and workshop in the city of New York, of the second part:

Witnesseth: That, whereas by a certain instrument of writing bearing even date herewith, the Electro-Dynamic Light Company, a corporation created and existing under and by virtue of the laws of the State of New York, assigned transferred and conveyed to the said William H. Church, all and singular the letters patent of the United States, dated and numbered as 3668 follows, viz: one dated June 25, 1878, and numbered 205,303, for "improvement in electric lighting systems;" one dated June 18, 1878, and numbered 205,144, for "improvement in electric lamps;" one dated June 25, 1878, and numbered 205,305, for "improvement in regulators for electric light;" one dated November 19, 1878, and numbered 210,152, for "improvement in switches for electric lights;" one dated December 10, 1878, and numbered 210,809, for "improvements in electric lamps;" one dated January 7, 1877, and numbered 211,262, for "improvement in carbons for electric lights;" one dated June 29, 1880, and numbered 229,335, for "carbons for electric lights;" one dated June 29, 1880, and numbered 229,476, for "improvement in electric switches;" one dated November 19, 1878, and numbered 210,151, for "improvement in electric meters;" one dated September 16, 1879, and numbered 219,771, for "improvement in electric lamps;"

one dated February 8, 1881, and numbered 237,632, for "dynamo electric machine," and also two undivided fifths of the whole of letters patent of the United States numbered as follows, viz: One dated August 14, 1877, and numbered 194,111, for "electric engineering and lighting apparatus and system;" one dated August 21, 1877, and numbered 194,500, for "electric candles;" one dated August 28, 1877, and numbered 194,563, for "electric lighting apparatus;" one dated November 6, 1877, and numbered 196,834, for "electric engineering and lighting systems;" which interest- in said last-mentioned letters patent were assigned by William E. Sawyer and Albon Man by a certain deed of assignment dated May 14, 1878, and recorded in Liber S 22, page 464, Transfers of Patents, and which interests in said patents were duly assigned by said Albon Man to said Electro-Dynamic Light Company by deed of assignment duly recorded in the Patent Office in Liber C 24, in pages 294, 295, 296 and 297, and dated, all of them, July 15, 1878; together with all and singular the 3669 inventions owned by said company and described, illustrated, claimed or suggested in said letters patent, owned by said company, any or either of them, whether owned by said company in whole or in part, and also all inventions owned by said company for which applications for patents are now pending in the United States, and also all assignments, covenants and agreements made by William E. Sawyer with Albon Man and assigned to said Electro-Dynamic Light Company, or which are now owned by said company, having reference to said patents and inventions, any or either of them, in which said company is now interested, in so far as the said covenants or agreements appertain to letters patents for said inventions, any or either of them, in the United States of America, but not elsewhere; for the said William H. Church to have, hold and enjoy for his own use, benefit and behoof, and for the use, benefit and behoof of his assigns and legal representatives, to the full end of the term for which the said letters patents have been or may hereafter be granted, issued, reissued or extended, any or either of them, in and for the whole of the United States and the territories thereof, and also

All covenants and agreements at any time made by the said William E. Sawyer and Albon Man, or either of them, jointly and severally, with the said Electro-Dynamic Light Company for the reissue or extension of said letters patents, any or either of them, or that in any way appertains to said patents and inventions or application for patents for the same in the United States of America, but not elsewhere, and that as fully and entirely as the same would, might or could have been held and enjoyed by the said Electro-Dynamic Light Company had said assignment and transfer not been made.

In trust nevertheless, for the said William H. Church to hold to the use and benefit of the said Electro-Dynamic Light Company, and especially to assign, transfer and convey to the 3670 said Eastern Electric Manufacturing Company of Middletown, Connecticut.

All and singular the said letters patents and inventions and applications for letters patent and the covenants and agreements aforesaid, the same to all intents and purposes as the said Electro-Dynamic Light Company conveyed the same to said William H. Church and his assigns.

The consideration for such deed from the Electro-Dynamic Light Company to said Church, being the said Church shall subscribe for nine-twentieths of the whole of the capital stock of the said Eastern Electric Manufacturing Company and pay for the same by transferring, conveying and assigning to said company the whole of the said letters patent, inventions, applications for letters patent, covenants and agreements aforesaid.

The said William H. Church is authorized by said deed to receive from said company the certificate or certificates of transfer of said stock of said Eastern Electric Manufacturing Company.

Now, therefore, the said William H. Church, having accepted the trust created by said deed, hereby covenants that he has subscribed for said nine-twentieths of the whole of the capital stock of the said Eastern Electric Manufacturing Company and that the certificate of transfer of said stock has been delivered to him by said company.

Wherefore, in consideration of said nine-twentieths of the whole of said capital stock of said Eastern Electric Manufacturing Company, the said William H. Church, as trustee for said Electro-Dynamic Light Company and its share and scrip holders has, and he does hereby assign, transfer and convey to the said Eastern Electric Manufacturing Company, all and singular, the aforesaid letters patents, and inventions and applications for letters patents, and all and singular the covenants and agreements so conveyed
3671 & 3672 to him by the Electro-Dynamic Light Company, as aforesaid, and that as fully and entirely as the same were conveyed to said Church by said deed, for the said Eastern Electric Manufacturing Company, its successors and assigns, to have, hold and enjoy for its and their own use, benefit and behoof absolutely through the whole of the unexpired term of said letters patent, any or either of them, and through all the renewals, reissues and extensions thereof.

In witness whereof the said William H. Church, trustee, has hereto set his hand and seal the day and year above written.

WM. H. CHURCH. [SEAL.]

AMOS BROADNAX.

3673 COMPLAINANT'S EXHIBIT NO. 17.

Assignment of Eastern Electric Manufacturing Co. to Consolidated Electric Light Co. of Patent in Suit. May 11, '86. T. G., Ex'r.

CONSOLIDATED ELECTRIC LIGHT CO.
vs. } H, 3553.
EDISON ELECTRIC LIGHT CO. *et al.*

Received for record Oct. 5, 1882, and recorded in Liber J 28, page 441 of Transfers of Patents.

In testimony whereof I have caused the seal of the [SEAL.] Patent Office to be hereunto affixed.

E. M. MARBLE,
Commissioner.

(Ex'd: M. T.)

This deed of assignment made this thirtieth day of September, one thousand eight hundred and eighty-two, by and between the Eastern Electric Manufacturing Company of Middletown, Connecticut, a corporation created and existing under and by virtue of the laws of the State of Connecticut, and having an office in the city of New York of the first part; and the Consolidated Electric Light Company, a corporation created and existing under and by virtue of the laws of the State of New York, and having its principal place of business in the city of New York.

Witnesseth: That whereas the said Eastern Electric Manufacturing Company is the owner of certain inventions and letters patent of the United States, hereinafter mentioned and designated.

3674 And whereas, by a certain instrument in writing, dated June 10th, 1882, and a certain supplemental agreement dated July 8th, 1882, the said Eastern Electric Manufacturing Company, for the consideration of four thousand and five hundred shares of the capital stock of said Consolidated Electric Light Company of the par value of one hundred dollars each, full paid and non-assessable, and for other consideration mentioned in said contract of July 10th, 1882, and said supplement of July 8th, 1882, agreed to convey to said Consolidated Electric Light Company all and singular the inventions, letters patent, rights and franchises now belonging to it, and belonging to it at the time of making said agreement of June 10th, 1882.

Now, therefore, in performance, of said agreement and in consideration of said four thousand and five hundred shares of the capital stock of said Consolidated Electric Light Company of the par value of one hundred dollars each, full paid and non-assessable, and for other consideration mentioned in said contract the receipt of which is hereby acknowledged.

The said Eastern Electric Manufacturing Company hereby assigns, transfers and conveys to the said Consolidated Electric Light Company all and singular the invention, letters patent, rights and franchises now owned by it, and owned by it at the time of making said contract of June 10th, 1882, and especially the joint letters patent of the United States granted to William Edward Sawyer and Albon Man, dated and numbered as follows, viz:

One dated June 25th, 1878, and No. 205,303;
One dated June 18th, 1878, and No. 205,144;
One dated June 25th, 1878, and No. 205,305;
One dated November 19th, 1878, and No. 210,152;
One dated December 10, 1878, and No. 210,809;
One dated January 7th, 1879, and No. 211,262;
One dated June 29th, 1880, and No. 229,335;
One dated June 29th, 1880, and No. 229,476.

3675 And also the letters patent granted to William Edward Sawyer, dated and numbered as follows, viz: one dated November 19th, 1878, and No. 210,151; one dated September 16th, 1879, and No. 219,771; one dated February 8th, 1881, and No. 237,632.

And also two undivided fifths of the whole of each of the following letters patent granted to William Edward Sawyer, viz:

One dated August 14th, 1877, and No. 194,111;
One dated August 21st, 1877, and No. 194,500;
One dated August 28th, 1877, and No. 194,563;
One dated November 6th, 1877, and No. 196,334.

And also the joint letters patent of the United States granted to William E. Sawyer and Edward R. Knowles dated May 10th, 1881, and No. 241,242.

And also the joint letters patent of the United States granted to William Edward Sawyer and Robert Street, dated and numbered as follows, viz:

One dated May 10th, 1881, and No. 241,430;
One dated August 23rd, 1881, and No. 245,976.

Also the joint letters patent of the United States granted to William Edward Sawyer and William Sawyer dated and numbered as follows, viz:

One dated December 14th, 1880, and No. 235,460;
One dated January 11th, 1881, and No. 236,460.

And also the letters patent of the United States granted to Thomas B. Stillman numbered and dated as follows, viz:

One dated March 23rd, 1880, and No. 225,730;
One dated April 20th, 1880, and No. 226,632;
One dated May 11th, 1880, and No. 227,454.

And also the letters patent of the United States granted to Edward R. Knowles, dated May 11th, 1880, and No. 237,365.

3676 And also the letters patent of the United States granted to William Sawyer, dated and numbered as follows, viz:

One dated February 17th, 1880, and N.o 224,612.

Six dated May 11th, 1880, and numbered respectively, 227,386; 227,387; 227,388, 227,389; 227,390 and 227,845.

Two dated May 25th, 1880, and numbered respectively, 228,122 and 228,123.

Two dated July 20th, 1880, and numbered respectively, 230,345 and 230,346.

One dated October 12th, 1880, and No. 233,234.

Two dated December 14th, 1880, and No. 235,385 and 235,459 respectively.

One dated February 8th, 1881, and No. 237,608.

Together with all and singular the inventions owned by said Eastern Electric Manufacturing Company and described, illustrated, claimed or suggested in said letters patent, any or either of them, and all interest in said letters patent, any or either of them, whether owned by said company in whole or in part, and also all inventions owned by said company for which applications are now pending in the United States and especially the application No. 547, filed January 9th, 1880, and all the divisions thereof; and also any and all applications which may be made, arise or grow out of, or in anywise appertain to any or either of said letters patent or applications for patents now pending.

And also all assignments, grants, licenses, covenants and agreements owned by said Eastern Electric Manufacturing Company in anywise appertaining to said patent-, any or either of them, or to any patents or inventions appertaining to electric lighting now owned by said company are hereby conveyed to said Consolidated Electric Light Company for the said company to have, hold or enjoy for its own use, benefit and behoof; and for the use, benefit and
3677 behoof of its successors, assigns and legal representatives to the full end of the term for which said letters patent are or may hereafter be granted, issued, reissued or extended any or either of them, in and for the whole of the United States and the territories thereof.

And also all the property and assets of every nature and kind whatsoever belonging to the said Eastern Electric Manufacturing Company and all which belonged to it at the time of making said contract of June 10th, 1880, is hereby transferred and conveyed to the said Consolidated Electric Light Company and that as fully and entirely as the same would or might have been held and enjoyed by the said Eastern Electric Manufacturing Company had this assignment and transfer not have been made.

And the said Eastern Manufacturing Company hereby covenants with the said Consolidated Electric Light Company that it is now the sole owner of the whole of said inventions and letters patent; that it has now the sole and exclusive right to the said inventions and to work said letters patent, subject only to the licenses and agreements hereinafter mentioned, the whole of which are hereby conveyed to said Consolidated Electric Light Company as aforesaid; and that said inventions and letters patent, are free, clear and not encumbered by, or for any claim, lien mortgage or demand whatsoever; and that it has good right and lawful authority to make and execute this deed of assignment and transfer in manner and form as aforesaid.

And said Eastern Electric Manufacturing Company hereby covenants with the said Consolidated Electric Light Company that the following and no other licenses and contracts under and appertaining to said patents have been made by it and are now outstanding, viz: A certain license dated March 1st, 1881, to the Commonwealth

Electric Light and Manufacturing Company, of Pennsylvania, and a certain supplement thereto, dated June 8th, 1882, granting the 3678 right to use said patents and inventions in the State of Pennsylvania. A certain license dated October 14th, 1881, to the Illinois Electric Manufacturing Company for the State of Illinois. A certain agreement by said company with A. J. Works, dated August 27th, 1880, appertaining to certain rights under the patents then owned by it in the District of Columbia and State of West Virginia.

The said Eastern Electric Manufacturing Company hereby conveys to said Consolidated Electric Light Company all its right, title and interest in and to said licenses and agreements, and all its rights of action thereunto appertaining both in law and equity, and all benefits and advantages growing out of the same.

The said Consolidated Electric Light Company taking this assignment subject to the conditions and advantages of said licenses and agreements.

And it is hereby covenanted and agreed between the said Eastern Electric Manufacturing Company and said Consolidated Electric Light Company, and this assignment is made upon this express condition.

That said Consolidated Electric Light Company shall not sell, lease or otherwise dispose of all its patents, patent rights and other rights and property to any individual or corporation, nor by lease, licenss or otherwise grant to any individual or corporation having an interest directly or indirectly in any other patents or system of electric lighting, any rights under said patents, nor permit the use or exercise of such rights by such individual or corporation without the consent in writing of holders of not less than five-sixths of the capital stock of said Consolidated Electric Light Company; and that all conveyances, grants and licenses made by said Consolidated Electric Light Company under said patents, any or either of them in violation thereof shall be absolutely null and void as being without authority and of no force or effect in law.

In witness whereof the said Eastern Electric Manufactur- 3679 ing Company has hereunto signed its name and affixed its seal the day and year first above written. The words "and agreements" in the fourth line of seventh page having been first interlined. Also on page three the words "and also the letters patent granted to William Edward Sawyer, dated and numbered as follows, viz: one dated Nov. 19th, 1878, and No. 210,151; one dated September 16th, 1879, and No. 219,771; one dated February 8th, 1881, and No. 237,632" having been first written in the margin, and the words "and all which belonged to it at the time of making said contract of June 10th, 1880," having been first interlined between the sixteenth and seventeenth lines on the sixth page.

THE EASTERN ELECTRIC MAN'F'G CO.,
By HORACE LITTLE, *President*.

Certificate of Incorporation of Electro Dynamic Light Co. *May* 11, '86.
T. G., Ex'r.

CONSOLIDATED ELECTRIC LIGHT CO. }
vs. } H, 3553.
EDISON ELECTRIC LIGHT CO. *et al.* }

We, Albon Man, William E. Sawyer, Hugh McColloch, Lawrence Myers, Jacob Hays, James P. Kernochan and William H. Hays, do hereby certify pursuant to the act entitled "An act to authorize the formation of corporations for manufacturing, mining, mechanical and chemical purposes," passed by the legislature of the State of New York, February 17th, 1848, and of the several acts extending and amending the same, that we desire to form, and hereby do form, a company to be known by the corporate name of "The Electro-Dynamic Light Company."

The objects for which said company is organized, are the production of light and power by means of electricity, the lighting of streets, buildings and other places, producing, conducting and distributing of electrical currents for lighting and other purposes and the manufacture and sale of all machinery necessary for and adapted to accomplish said objects, and the purchasing and holding of such property real and personal as may be lawful and necessary in the proper transaction of the said business.

The capital stock of said company shall be and is ten thousand dollars, in two hundred shares of fifty dollars each.

The term of existence of said company shall be fifty years from the date of this certificate.

The number of trustees of said company shall be seven and the names of the trustees who shall manage the business of the 3683 corporation for the first year are Albon Man, William E. Sawyer, Hugh McCulloch, Lawrence Myers, Jacob Hays, James P. Kernochan and William H. Hays, all of whom are citizens of the United States and of the State of New York.

The operations of the company are to be carried on in the city and county of New York, and State of New York.

Dated July 8th, 1878.

CONSOLIDATED ELECTRIC LIGHT CO.
vs.
EDISON ELECTRIC LIGHT CO. *et al.* } H, 3553.

STATE OF CONNECTICUT,
OFFICE OF SECRETARY OF STATE.

The Eastern Electric M'f'g Company.

Certificate of Organization.

To all persons to whom these presents may come:

The undersigned being the president and a majority of the directors of the Eastern Electric Manufacturing Company, a corporation organized under the statute laws of the State of Connecticut regulating the formation of joint stock corporations, and located in the town of Middletown, in the county of Middlesex, in said State, in pursuance of said statute laws, hereby certify as follows, to wit:

1st. The purposes for which said corporation is formed are the following, to wit:

To purchase letters patent of the United States and other countries, issued for improvement in electrical machines, or for the use and application of electricity; to manufacture and sell electric machines, to manufacture and sell machines or the generation or production of electricity; to manufacture and sell machines for the production of power by electricity; the production of power, heat and light by electricity; the lighting of cities, towns, villages, private residences and other places by electricity; the manufacture and sale of electrical signals for railroads and other 3686 purposes; the manufacture and sale of electrical machinery and apparatus relating to telegraphy; the construction and management of telegraph lines, the discovery and application of new uses for electricity and galvanism in the arts and sciences; the licensing and sale of rights to use such letters patent as the said corporation may own or be entitled to, to individuals, towns, cities or corporations; and to buy and sell and deal in any real and personal estate necessary or convenient for the prosecution of said business; and generally to do all things incidental to said business and the proper management thereof.

2nd. The amount of their capital stock actually paid in is two million dollars.

3rd. The amount of their capital stock actually paid in is two million dollars.

4th. The names of their stockholders and the number of shares by each respectively owned is as follows, to wit:

Names of stockholders.	No. of shares.
William Sawyer, New York	6,666
Horace Little, Ridgeway, Penn	6,667
Joseph Goodrich, Jr., Haverhill, Mass	2,222
Daniel J. Noyes, New York	2,223
John J. Anderson, New York	2,222

And in further pursuance of said statute laws, we cause this certificate to be deposited with the secretary of this State, and a duplicate thereof with the town clerk of the town of Middletown, in which said corporation is to transact its business.

Dated at Middletown, this 15th day of January, A. D., 1880.

EDISON ELECTRIC LIGHT CO. *et al.*

Certificate of incorporation of the Consolidated Electric Light Company.

STATE OF NEW YORK, } *ss:*
City and County of New York,

We the undersigned Horace Little, Edwin S. Thayer and John P. Adams do by these presents pursuant to and in conformity with the act of the legislature of the State of New York, passed on the seventeenth day of February, in the year one thousand eight hundred and forty-eight entitled "An act to authorize the formation of corporations for manufacturing, mining, mechanical and chemical purposes" and the several acts of the said legislature amendatory thereof, associate ourselves together and form a body politic and corporate and do hereby certify:

ARTICLE I.

That the corporate name of the said corporation is The Consolidated Electric Light Company.

ARTICLE II.

That the objects for which said corporation is formed are as follows: To manufacture, use, lease and vend, and license to 3689 use, lease and vend, machinery, implements, fixtures, tools and utensils for the production and maintenance of electric lights, and for the production and utilization of electricity for other purposes, and to buy, sell, lease, occupy, use and deal generally in such estate real, personal and mixed as the purposes of the corporation may require.

ARTICLE III.

That the capital stock of said corporation shall be twelve hundred thousand dollars.

ARTICLE IV.

That the said capital stock shall be divided into twelve thousand shares of one hundred dollars each.

ARTICLE V.

That the said corporation shall commence on the eight- day of September, A. D. one thousand eight hundred and eighty-two, and shall continue in existence for the term of fifty years.

ARTICLE VI.

That the number of trustees of the said corporation shall be thirteen and the names of those who shall manage its concerns for the first year are Horace Little of Ridgway, Pa., Hugh R. Garden of Warrentown, Va., Thomas Wallace of Ansonia, Conn., Preston B. Plumb of Topeka, Kansas, Henry T. Jenking of New York, N. Y., Jacob Hays of New York, N. Y., Albon Man of Brooklyn, N. Y., William Windom of Winona, Minnesota, Amos Broadnax of Brooklyn, N. Y., Edwin S. Thayer of New Bedford, Mass., Herbert L. Judd of New York, N. Y., John J. Anderson of New York, N. Y.; William Richardson, of New York, N. Y., all of whom are citizens of the United States and a majority of whom are citizens of the State of New York.

ARTICLE VII.

3690 That a part of the operations and business of the said corporation will be carried on out of the State of New York and that the princip*le* place of business of the said corporation within said State will be in the city and county of New York.

Dated New York, September 7, A. D. 1882.

3692 COMPLAINANT'S EXHIBIT NO. 22.

Edison's patent, No. 341,644.

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company of New York, N. Y.

Incandescent Electric Lamp.

Specification forming part of Letters Patent No. 341,644, dated May 11, 1886. Application filed May 31, 1881. Serial No., 34652. (No model.)

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful improvement in electric lamps; and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawings, and to the letters of reference marked thereon.

The object I have in view is to produce a simple method and means for sealing incandescent electric lamps, so that when the carbons are destroyed the lamps can be taken apart, supplied with new carbons, and again exhausted and sealed at a less cost than the first expense of manufacture. This I accomplish by providing the glass support for the filament of each lamp with a sufficiently large ground surface with which fits closely a ground surface of similar size on the globe or bulb, one or both of the surfaces being, if necessary, first covered with a viscous substance, which fills the interstices and makes an air-tight joint. The lamp is exhausted, as usual, and the pressure of the atmosphere holds the surfaces together, the viscid substance requiring no packing to hold it in place.

3693 As just stated, the lamp is made in two glass parts secur together by a ground glass joint aided by atmospheric pre ure. The wires leading to the incandescing conductor are seale into one of the glass parts of the lamp by the fusion of the gla around and upon such wires. For the incandescing conductor the is employed a carbon filament—viz., a conductor of carbon of filamentary size, and having consequently a high resistance, which permits of the use of small leading-in wires, which can be successfully sealed into the glass without danger of breaking the seal at such points.

The lamp globe, it will be understood, is exhausted by connection with suitable vacuum apparatus, and is "sealed off" from connection with the vacuum apparatus by the fusion of a glass tube extending from one glass part of the lamp.

(No Model.)

T. A. EDISON.

INCANDESCENT ELECTRIC LAMP.

No. 341,644. Patented May 11, 1886.

} p 3695

Fig. 2.

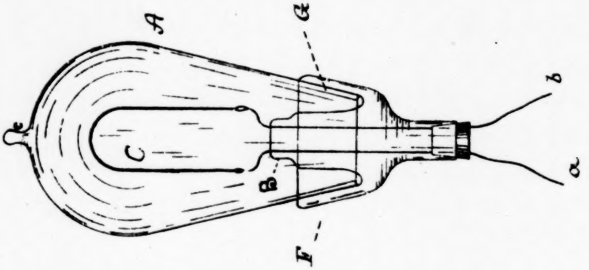

Fig. 1.

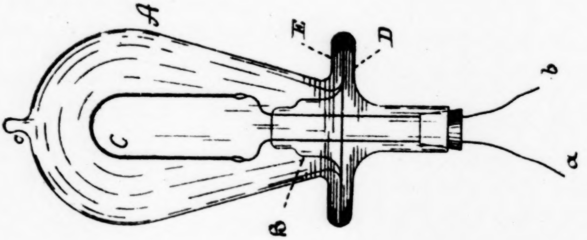

Attest:

S. D. Mott

N. W. Seely

Inventor:

T. A. Edison

per

Dyer & Wilber

Attorneys

The lamp produced is separate from the vacuum apparatus, and has each of its two glass parts formed of a continuous glass piece by the fusion of the glass, the only point in the glass globe where the glass tube is not fused into one piece being at the ground surfaces where the two parts meet.

In the drawings,

(Here follows diagram marked p. 3695.)

Figure 1 is an elevation of one form of the lamp embodying my invention, and Figs. 2 and 3 elevations of other forms.

A is the glass globe or bulb. B is the glass support for the filament; *a b*, the leading-in wires, and C the incandescing carbon filament.

In Fig. 1 the glass support is shown as provided with a solid horizontal flange, D, which is ground on its upper surface, while the bulb, A, at its lower end, is turned outwardly to form a horizontal flange, E, which is ground on its under surface and fits closely the upper surface of the flange D. Before the bulb A is exhausted the carbon is inserted into the same and the ground surfaces of the flanges D E brought together, one or both of such surfaces being first rubbed by a viscid substance—such as
3694 bird-lime, paraffine, or liquid rubber or grease. The bulb is
then exhausted, as usual, and sealed off at *c* by the fusion of the glass.

In Fig. 2 the glass support has an upturned cup flange, F, and the lower end, G, of the bulb is fitted inside of the same, the meeting surfaces being ground. A viscid substance is used in the joint, as before explained. The end, G, of the bulb may be fitted over the cup, F, if desired.

In Fig. 3 the lower end, G, of the bulb is fitted over the tapering body, A, of the glass support. When the carbon is broken the globe may be used over again. It is opened by breaking off the sealing teat, *c*, allowing the air to rush into the vacuum. The globe can then be separated at the joint. A new exhausting tube is sealed on where *c* is broken off, a new carbon filament is connected with the wires, and the globe is exhausted and again sealed.

What I claim is—

1. A separate incandescent electric lamp consisting of an exhausted glass inclosing chamber made in two parts, each of which is formed of a continuous glass piece by the fusion of the glass, the two parts being provided with ground meeting or junction surfaces aided in their adhesion by atmospheric pressure, and an incandescing carbon filament secured to leading-in wires passing through one of the parts, and sealed by fusion into the glass thereof, substantially as set forth.

2. A separate incandescent lamp consisting of an exhausted glass inclosing chamber made in two parts, each of which is formed of a continuous glass piece by the fusion of the glass, the two parts being provided with ground meeting or junction surfaces covered with a viscid substance, and aided in their adhesion by atmospheric

pressure, and an incandescing carbon filament secured to
3696 leading-in wires passing through one of the parts, and sealed
by fusion into the glass thereof, substantially as set forth.

3. A separate incandescent electric lamp consisting of an exhausted glass inclosing chamber made in two parts, each of which is formed of a continuous glass piece by the fusion of the glass, the two parts being provided with ground meeting or junction surfaces aided in their adhesion by atmospheric pressure, and one of such parts having the sealing teat, *c*, and an incandescing carbon filament secured to leading-in wires passing through one of the parts and sealed by fusion into the glass thereof, substantially as set forth.

This specification signed and witnessed this 20th day of May, 1881.

3697 COMPLAINANT'S EXHIBIT NO. 23.

Edison's patent No. 263,878.

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company of New York, N. Y.

Electric Lamp.

Specification forming part of Letters Patent No. 263,878, dated September 5, 1882. Application filed December 15, 1880. (No model.)

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful improvement in incandescent electric lamps (case 271); and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawing, and to the letters of reference marked thereon.

My invention relates to that class of electric lamps in which the light is caused by the incandescence of a carbon filament, and has for its object the production of an arrangement which will maintain a vacuum in the globe which contains the carbon.

In prior applications and patents I have shown methods of sealing the various parts of the lamp together by a fusion of the glass itself, thereby forming at the joints a vitreous seal of the same character and durability as the body of the lamp itself. Under some circumstances an unfused seal may be sufficient, the parts being put together so that while a joint practically tight for a limited period is secured they may, when desired, be separated. To 3698 accomplish this may be stated as the special object of the invention hereinbefore set out in more general terms. My arrangement for this purpose consists in setting the globe in a glass socket, both being ground, so that they will fit tightly together. Afterward, the space left being filled with mercury and a packing of rubber used to close the whole tightly and retain the mercury in the space, the air is exhausted from the globe at its top, which is then sealed, so that a vacuum is maintained.

The accompanying drawing is a sectional view of a lamp constructed according to my invention.

(Here follows diagram marked p. 3699.)

W is an insulating base, usually of wood. A is the glass socket fitting therein. It is, when seen in section, somewhat of the form of the letter W, the central limb being extended upwardly and forming a support for the wires leading to the clamps, the wires being suitably sealed therein, this central portion extending up within the body of the globe B. The socket A is ground at *a* and the globe B correspondingly ground at *b*, so that they fit tightly together. A space C, is thus left, which is filled in with mercury, forming a liquid seal. Above the mercury is placed a rubber ring, D, which fits tightly and prevents the mercury from escaping.

1 2 are the wires of the circuit, by which electricity is supplied to the lamp. These wires terminate in the platinum clamps *c*, which hold the carbon. A portion of the circuit is formed by the screw *d*, which may be drawn back to break the circuit and extinguish the lamp, or *vice versa*.

After the globe B is blown a stem remains at *x*, by means of which the air is exhausted, and the globe is then sealed and the stem broken off, leaving the globe perfectly air tight and keeping a vacuum in its interior.

What I claim is—

3700 1. The central tube conductor or support for the incandescing conductor, formed with a chamber at its base and fitted to receive tightly therein the neck of the inclosing globe, substantially as set forth.

2. In an incandescing lamp, the combination of the chambered central tube or support and the inclosing globe, ground or adapted to fit tightly, substantially as described.

3. The combination, in an incandescing lamp, of the chambered central tube or support adapted to hold a liquid seal, the inclosing globe having a neck fitted to the chamber, and a packing for securing the liquid seal, substantially as set forth.

This specification signed and witnessed this 3d day of December, 1880.

3701 & 3702 COMPLAINANT'S EXHIBIT NO. 24.

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company of New York, N. Y.

Incandescent Electric Lamp.

Specification forming part of Letters Patent No. 264,657, dated September 19, 1882. Application filed August 30, 1881. (No model.)

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful improvement in incandescent electric lamps (case No. 322); and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawings, and to the letters of reference marked thereon.

The object I have in view is to produce another form of incandescing electric lamp which can be taken apart when the carbon is destroyed and the principal parts again utilized. This I accomplish by providing the lower end or neck of the glass bulb or globe with a ring of platinum, which is sealed into the glass of the globe and is soldered to another platinum ring sealed into the glass of the wire support. After the platinum rings are soldered together the globe is exhausted and sealed. When the carbon is broken the platinum rings can be separated by melting the solder by heat, or eating it away with acid, and the parts can be used over again, it being only necessary to supply a new carbon filament, to solder the platinum rings together again, and to re-exhaust and reseal the globe. For this last purpose the globe
3704 will be heated at the top, and will be perforated and provided with a glass tube for making connection with a suitable exhausting apparatus.

In the drawings,

(Here follow diagrams marked pp. 3703 and 3705.)

Figure 1 is a view of the lamp complete, and Fig. 2 a vertical section of the two parts of the lamp before the platinum*s* rings are soldered together.

A is the glass globe; B, the glass wire support; C, the carbon filament, and *a b* the leading-in wires. D is a platinum ring, sealed to the glass at the lower end of the neck of the globe, and E is another platinum ring, which is dropped over the upper end of the glass wire support, and sealed to the glass of the enlarged portion of the wire-support. One of these rings is preferably smaller than the other, so that they fit closely over the other. These platinum rings are soldered together before the lamp is exhausted. To separate the two glass portions of the lamp, the solder can be melted or eaten away by acid.

It will be understood that the tubular glass wire support B is hermetically sealed at its upper end by being flattened and fused upon the leading-in wires *a b*, such leading-in wires passing out through this tube. After the globe A is hermetically sealed at its lower end, and secured to the support B by the soldering of the platinum rings D E together, the lamp is exhausted by means of the glass tube attached to the globe, which is sealed off by fusion of the glass. The joints between the platinum rings and the two glass portions of the lamp are made air tight by the fusion of the glass upon such rings.

What I claim is—

1. In an incandescing electric lamp, the combination, with the two portions of the lamp made entirely of glass, of a joint between said parts, composed of two platinum portions attached to the glass parts by the fusion of the glass upon them, said platinum
3706 portions being hermetically secured together, substantially
as specified.

2. In an incandescing electric lamp, the combination of the two portions of the lamp made entirely of glass, the carbon filament supported from one of said glass portions by leading-in wires passing through and sealed into the glass by the fusion of the glass thereon, and a separable metallic joint between the two glass portions of the lamp, substantially as specified.

3. In an incandescing electric lamp, the combination of the two glass portions with the lamp of the carbon filament supported from one of said glass portions by leading-in wires passing through and sealed into the glass by the fusion of the glass thereon, a sealed glass exhausting tube on one of said glass portions, and a separable metallic joint between the two portions of the lamp, substantially as specified.

4. In an incandescing electric lamp, the combination, with the glass globe A, of a tubular glass wire support, B, extending up into the globe and hermetically sealed at its upper end upon the leading-in wires, and the platinum rings D E, secured to the lower end of the globe and to the sides of said tubular support by the fusion of the glass upon said rings, such rings being secured together to form a separable air-tight joint, substantially as specified.

This specification signed and witnessed this 21st day of May, 1881.

Canadian Patent No. 11968. *Issued to Thomas Alva Edison for "Edison's Electric Lamp," November* 11, 1880.

Department of agriculture, patent office.

OTTAWA, CANADA, *August* 7, 1885.

Certified to be true and correct copies of the original petition and oath remaining on record in this office of Thomas Alva Edison, relating to his application for a patent, and on which patent was granted to the said Thomas Alva Edison, bearing date the eleventh day of November, 1880, for "improvements on electric lamps, and in carbons or incandescing conductors therefor, and in means for and methods of manufacturing the same," and that said petition and oath were filed in this office October 20th, 1880.

[L. S.] As witness the seal of the patent office hereto affixed.

A. J. CAMBIE,
Acting Deputy Commissioner of Patents.

3708 *Petition.*

To the commissioner of patents, Ottawa :

The petition of Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician, showeth : That he hath invented new and useful improvements on electric lamps, and in carbons or incandescing conductors therefor, and in means for and methods of manufacturing the same not known or used by others before his invention thereof, and not being in public use, or on sale for more than one year previous to his application in Canada, with his consent and allowance as such inventor, the title or name whereof, is Edison's electric lamps, and means and methods for manufacturing the same.

Your petitioner therefore prays that a patent may be granted to him for the said invention ; and, for the purpose of the patent act of 1872, your petitioner elects his domicile in the city of Ottawa, Province of Ontario, Canada.

And your petitioner hereby appoints L. W. Serrell of New York, N. Y., or his associate, T. G. Coursolles of Ottawa, Canada, his attorney, with full powers of substitution and revocation, to prosecute the present application for patent, to sign the drawings, to receive the patent, and to transact all business in the patent office, connected therewith.

Signed at New York, this 8th day of October, 1880.

(Signed) THOMAS ALVA EDISON.

In the presence of—
(Signed) GEO. T. PICKNEY.

3709 *Oath.*

UNITED STATES OF AMERICA,
State of New York, County of New York.

I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, United States of America, electrician, make oath and swear that I verily believe that I am the first inventor of new and useful improvements in electric lamps, and in carbons or incandescing conductors therefor, and in means for, and methods of manufacturing the same described and claimed in the annexed specifications, and for which I solicit a patent by my petition, dated October 8th, 1880.

And I further make oath that the several allegations contained in said petition are respectively true and correct.

THOMAS ALVA EDISON.

Sworn before me at New York, State of New York this eight day of October, 1880.

GEO. T. PINCKNEY,
Notary Public.

Certified that the annexed is a true copy of a patent registered in the patent office under number (11968) granted to Thomas Alva Edison, and bearing date the eleventh day of November, 1880, for "Edison's electric lamp, and means and methods for manufacturing the same," with true copies of the specification and drawings remaining on record in this office, duplicate copies of which were attached to the patent above mentioned.

3710 Department of agriculture, patent office.

OTTAWA, CANADA, *July 31st*, 1885.

As witness the seal of the patent office hereto affixed.

A. J. CRAMBIE,
[L. S.] *Acting Deputy Commissioner of Patents.*

Specification.

To all whom it may concern:

Be it known, that I, Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician, have invented certain new and useful improvements in electric lamps and in carbons or incandescing conductors therefor, and in means for and methods of manufacturing the same. As is now generally known, I prefer to use in my system of electric lighting, an electric lamp consisting essentially of an incandescing conductor, sealed hermetically in a glass-inclosing globe. In manufacturing carbons for such and for all classes of electric lamps, the practice, so far as I know, has been to make them of as low resistance as possible, a porous carbon having been used which was dipped or soaked in some carbonizable liquid

until its pores were filled and then subjected to recarbonization, which process was repeated until the pores of the original carbon were filled with carbon. By this process the resistance of the carbon is lessened, while its liability to disintegration under high heat is increased. Such carbons are unfit for use in electric lamps giving light by incandescence. For such lamps I have discovered that the incandescing material should have the highest possible resistance in a very small bulb, and be capable of resisting the disintegrating effects of very high heats and the absence of atmospheric
3711 pressure; and further, that carbons, which are purely structural in character, alone possess these qualities. By purely structural is meant a carbon wherein the natural structure, cellular or otherwise, of the original material is preserved unaltered; that is, not modified by any treatment which tends to fill up the cells or pores with unstructural carbon or to increase its density, or to alter its resistance.

One object of this invention, therefore, is to provide such carbons and means and methods for their manufacture.

In practice, the incandescing conductor of a lamp should be of about one hundred *omhs* resistance. While this may be varied within certain limits, the resistance stated is a preferable one and is a very high resistance compared to the carbons referred to as previously used. It is essential that the high resistance should be had without increase of radiating surface, that is, only the radiating surface necessary to give a certain standard amount of light at the proper degree of incandescence should be used. I have discovered that incandescing conductors possessing the qualities enumerated may be made of such natural fibres or fibrous bodies as are capable of carbonization, especially such as are large, filamentary and cellular in character.

Of such there are several varieties, of some of which a single fibre or several fibres aggregated together artificially are used; of some, a piece composed of numerous elementary fibres are used.

I have found that the preferable single fibres are those of which jute, bast, manila, hemp, etc., are good types, the most preferable one being a fibrous grass from South America, called "monkey bast" fibre, each blade of which is generally round, and composed of a great number of elementary fibres held together by a natural cement or rosin, which, carbonizing, locks all the elementary fibres together into a homogeneous filament. The treatment next herein described applies, however, to all the fibres of this class.

3712 These blades vary somewhat in size, and are also slightly tapering. It being necessary that the conductors should be of an uniform size, I reduce them and also any other fibres varying in size to uniformity by passing them through a cutting die which shaves off the extraneous matter or a revolving cutter may be passed along the fibre or they may be reduced in any other practical way.

When desired I may take several fibres of the above-named grass, or several of any other natural fibres, and after bunching them together dip them into a solution of sugar or other carbonizable liquid and then carbonize as one fibre, the carbonized cementing liquid binding them firmly together into a large filament of higher resistance, but of no greater radiating surface than the carbonized paper incandescing conductor heretofore described by me.

So far as capable of illustration this part of the invention is shown in Figs. 1, 2 and 3. Upon the ends of the fibre, *A*, whether simple or compound, are fixed prior to carbonization, the clamps, *B*, made of any suitable carbonizable material, lignum-vitæ, boxwood, etc., being well adapted therefor. They may be made flattened or square, but preferably are cylinders. A small hole is bored through the centre and the fibre inserted therein, as shown in Fig. 2.

It is advantageous to moisten the inserted ends of the fibre with a solution of sugar or with other carbonizable liquid. Pieces of platinum wire, *c*, *c*, are inserted into the clamps as shown in Fig. 1.

Upon carbonization, the material of clamps, *B*. *B*, shrinks around and upon the wires and fibre binding them tightly together, which result is aided by the carbonization of the liquid, applied as before suggested to the inserted ends of the fibre.

Of those materials wherein the piece necessary to form a conductor is composed of a large number of fibres, I have discovered that excellent results pertain to the use of the plants of the family *Arundenerra* or Gigantic grasses, commonly known as bamboo or 3713 cane or cane bamboo. In such, the primary fibres making up the mass of the material extends from end to end, parallel to each other, increasing the strength and obviating danger of breakage from cross or oblique grain.

Of the bamboo cane the hard, glossy exterior is the best to use, and the softer or pithy part should be rejected. To produce the best results, in giving light, it is essential that the carbons should be of uniform size throughout the portion that is to be rendered incandescent in order that the radiating surface and resistance be regular and uniform insuring even heating and incandescence.

To accomplish this the cane bamboo or other material used is treated as follows, and by the following means: The cane is split into pieces somewhat wider than necessary, and the inner or pith portion removed. The material chosen (either the case or bast, or other if desired), cut into strips, is passed through a shaving device in which a cutting or shaving knife is fixed, the material being forced against the knife by a movable block provided with an adjustable stop-screw by which the distance of the block from the knife can be regulated, regulating in turn the thickness to be given to the slip. In this device the slip or filament is shaved on both sides until the proper thickness is attained.

It is then placed in a clamp composed of two halves of a length equal to the desired length of the slip. In one half a shoulder or offset is formed at a distance from the edge greater than the desired width upon which one edge of the fibre rests which is then clamped between the two halves and the protruding portion carefully shaved off, which may be done by hand or by a cutting blade moved by machinery. On the opposite side of the clamps is an offset in one half, at a distance from the edge exactly equal to the width to be given the slip.

As it is desirable to form the extended bearing upon which
3714 take the clamps securing the carbon to metallic conductors,
homogeneous and in one piece with the body, provision is
made therefor.

Upon the side last referred to of the clamps and at the ends, are made projections of the exact shape and size to be given the broadened ends of the carbons. The slip shaved upon both sides and one edge is transferred to the opening in the clamps and the extra material shaved or cut off. The slip is now of uniform size throughout its body, and with enlarged ends formed upon it. The enlarged ends are entirely upon one edge instead of the enlargement being equally distributed upon both edges. This construction enables the slips when placed on edge—the straight edge—in the carbonizing flask to move therein as they are contracted in the process of carbonization.

This part of the invention is illustrated in Figs. 4, 5, 6, 7 and 8, in which Fig. 4 is a top view and

Fig. 5 is a side view of the device used for shaving the sides. Fig. 6 is an end view and Fig. 7 a side view of the clamps used in shaving the edges. Fig. 8 is a view of a complete filament.

In these figures, *A* is a suitable base, having upon its supports, *a*, *a*^{1}, for the working devices, these supports leaving an open space between them in which such working devices are mainly located.

In front of *a*^{1} is fixed a block, *B*, fashioned at one end to receive and support at the proper angle the knife or plane, *b*. In front of *A* is a block, C, attached to screw *D*, sliding in *A*, and caused to rotate so as to move *C* by disc *E*, working in a slot in *a*. *D*, being prevented from rotating by screw *d*, taking into a feather cut in its side.

Upon the side of *C* is lug *G*, through which passes the screw, *g*, which is set to strike against *B*, and consequently limit the movement of *C*, keeping it at any desired distance from *B*, which distance is the thickness intended to be given the slip.

The slip S, is placed between B and C, and drawn through
3715 between them, being forced by C, against the edge of the
knife until one side is smoothed. It is then taken out and
replaced with the shaved side next to C, and the operation repeated.
By these operations and means the slip is reduced to an uniform
thickness.

The clamp for reducing to an uniform width is made of two parts H, I, of a length equal to the length to be given to the slip, and held together by pieces *x*, one at each end having a slot *o*, in one end so as to permit of a limited movement of the parts H, I, from each other.

The part I, is formed with shoulders or offsets *v*, *w*, along its entire length, taking into a corresponding recess in H, forming when the two parts are in position slots along the entire length of the clamp, the offsets *v*, *w*, forming the bottom of the slots.

Upon one side at each end of each part are formed the lugs or projections *h*, *h*, the size and shape of the enlarged ends of the finished carbons.

In *h*, *h*, are the small recesses *i*, *i*, for the purposes hereinafter set forth.

The slip S, of a greater width than the widest portion of the finished slip is placed in the clamp in the slot whose bottom is the offset *v*, the clamps tightened and the protruding portion removed down to the surface of the clamps.

The edge thus prepared forms a straight edge, a gauge for the finishing, the slip being placed in the clamp in the slot whose bottom is the offset *w*, and the extra material removed on the line formed by the surface of the clamp, and the projections *h*, *h*.

This being done a saw or knife is run through the recesses *i*, *i*. The result is the slip shown in Fig. 8, having an uniform body with the enlarged clamps for securing the carbon in the clamps and provided with the recesses *i*, which are of use in securing the slip in the carbonizing flask, and afterwards for permitting the clamping screws to pass through.

Sometimes it is desirable to form the ends thicker in both directions. In such cases the preliminary cutting in the first 3716 machine simply reduces the slip to dimension equal to the desired width and thickness of the ends, and it is then finished off in the clamps, one set of clamps being made with shallow grooves so that the slip might be laid flatwise therein.

Good, natural and purely structural carbons may be made of wood as the wood is an example of the class of materials alluded to in which the mass of the material is composed of a number of elementary fibers naturally bound together.

In all instances the wood is first to be formed into the shape of what is generally known in my system as the loop or horseshoe and carbonized and not to be subjected to any further processes which will tend to fill up its pores and alter its density or resistance.

The wood may be prepared by several methods; for instance it can be shaped by cutting or stamping by a die. A thin veneer of wood properly smoothed and brought to the desired thickness is taken and laid upon a mold or bed plate, a cutting die is then forced down upon it, cutting out a piece in the desired shape for the incandescing material and with thickened ends for attachment to the clamps, or a number of veneers may be taken and secured together, and then cut into proper shape by a band, jig or circular saw.

This is illustrated in Fig. 9, which is a section of the cutting die and mold with a veneer in position, and in Fig. 10 which shows the resultant piece ready for carbonization. In these figures A, is a cutting or stamping die provided with the cutting or stamping edge *a*, projecting from the face of A, and of the same size and contour as the wooden horseshoe E. B is the mold or bed plate, having a groove or recess D, whose upper edge is of a size and shape just sufficient to receive *a*, but increasing in size towards the base to permit the ready escape of anything which may be forced in at the top. C is a piece of veneer in position for the operation of the stamp or die A.

Upon force being applied to A, shoe E is cut from the wood
3717 with the broadened ends *c*, for attachment to the clamps
homogeneous and unitary therewith. This is then taken and placed in a suitable carbonizing flask fully illustrated herein. The result is a porous structural carbon of high resistance, excellently fitted for use in lamps intended to give light by incandescence, and not needing any further treatment which might alter or modify its purely natural structure. Another method is as follows:

A block of wood is taken and cut or formed, so that its centre shall be a web bounded at the sides by thicker portions. The grain of the wood is from side to side, and the thickness of the web is about the desired breadth of the carbon.

From the block so fashioned, pieces whose width approximate the desired thickness of the carbon are split, shaved or cut off. These pieces are then sufficiently softened by moisture and heat so as to be bent into a circular or horseshoe or oval form, and they are retained in such shape in a proper carbonizing flask and carbonized. This method is illustrated in Figs. 11, 12 and 13, in which Fig. 11 represents a block formed as before described, Fig. 12 a piece, split, cut or shaved therefrom, and Fig. 13 the same after carbonization, in which A is the web of the block, the centre of the block being reduced in thickness, while the ends *a*, *a*, are left broad or thickened for fastening to the clamps. This block is split, cut or shaved into pieces like Fig. 12, which are then bent into the shape shown in Fig. 12 or into any other desirable shape, and then carbonized while in such form. The result is a carbon with broadened ends for clamping unitary with itself, and which is porous, structurally unaltered, of high resistance and with a minimum tendency to disintegration under high heat. It is evident that the block shown in Fig. 11 could be made of disintegrated fiber, paper, pulp, papier maché, etc., by powerful pressure, and the individual carbons then cut off from such block, but in practice I so far prefer to make the block and resultant carbons of wood.

3718 Another method is as follows :—

A block of wood is taken and cut in a milling machine or lathe for turning irregular forms; until the shape is that of an elongated oval, of which about one-third, including an end is cut upon somewhat larger axes than the remainder, in order to provide for the clamps. The interior is then reamed out in a suitable machine, so that the block then resembles a series of carbon horseshoes with closed ends, piled upon each other.

The length of the oval is with the grain of the wood. The block is then split or sawed into very thin layers or slips, each forming ultimately one horseshoe carbon. The slips are then carbonized preferably in a nickel flask of a description shown herein; after carbonization the greater portion of the broader end of the slip is cut off, leaving the horseshoe in shape for use. This broader end which connects what are afterwards the ends of the horseshoe, may, if desired, be cut off prior to carbonization, but as this broader connecting end tends to support and keep in shape the portions afterwards forming the horseshoe, it is better to leave it on until after carbonization.

Either before or after carbonization, preferably before, and before the slips are sawed or split from the block, small holes are made in the broad end through which pass the clamp-screws.

This is illustrated in Figs. 14, 15 and 16, of which

Fig 14 is a perspective view of the block partially turned in proper shape.

Fig. 15 is a front view of a carbon after carbonization.

Fig. 16 is a side view of a carbon properly secured in clamps.

3719 In these figures A is a block of wood which in a proper machine is turned so that its exterior shape is that of an oval, composed of two ovals, B, C, of different axes, thereby forming a broader portion for the clamps, the interior being reamed out to present a uniform smooth surface F. This block so shaped is then split or sawed into very thin layers or slips of a thickness sufficient for one carbon horseshoe, as seen in Figs. 15 and 16. These slips are then carbonized and a portion of C broken or cut off at *c c*, as shown in dotted lines in Fig. 15.

At some stages in the process, preferably while in the shape shown in Fig. 14, holes, *d d*, are drilled for the reception of the screws *e*, which fasten the clamps *d* to the carbon.

It is desirable in manufacturing carbon slips, or filaments of the style generally known as the horseshoe carbons for use as the incandescing conductors in electric lights, that they should be carbonized evenly and uniformly, and that their shape should be preserved, that the carbonization should be effected without warping or twisting the body of the carbon.

As, however, the material contracts largely in the process of carbonization, means are required which, while holding the material in position to avoid twisting or warping, shall at the same time guarantee even and thorough carbonization and permit the material to move so that the inevitable contraction during the process may proceed without danger of rupturing or otherwise damaging the carbons. For this purpose means and methods as follows are used:

For fibers of the class where a single fiber is used, and clamps or enlarged portions for clamps are secured thereto, a carbonizing flask is used in the bottom of which is cut a groove approximating in form the shape desired for the finished carbon, but somewhat longer, in which groove is laid the fiber with its attached clamps.

3720 A heavy metal-ic cover is then laid thereon, confining the fiber in place, so that it preserves its shape during carbonization, while at the same time it is free to contract. The cover may in turn be grooved and receive another fiber, and a series be used so that many may be carbonized at once in one flask. This flask and all its parts should be made of nickel, which is best adapted to stand the high heats necessary to thorough carbonization. This flask is illustrated in Fig. 17, in which D is a flask or box of metal, capable of withstanding a high degree of heat, having a groove, E, of the desired shape cut in its bottom, as shown in Fig. 17. As fibrous material contracts or shrinks in the process of carbonization, it is necessary to provide for the movement attendant thereon, care being taken at the same time to prevent any movement which would allow of warping or distortion. This is effected by the groove E, which allows a longitudinal movement but prevents any other.

In this groove the fiber with its attached ends is placed, a cover F being then laid over it. A corresponding groove may be cut in the upper surface of the cover F, and another fiber laid therein, and a number of such covers, limited by the capacity of the flask or box D, may be used, so that many may be carbonized at one operation. When the flask or box E is full, the lid F is fastened tightly thereon, and the whole placed in any suitable furnace for carbonization. The result is what is now known as the horseshoe carbon made as a single fiber, with carbon clamps and proper conductors securely attached thereto by the process of carbonization.

As these carbon clamps, from their much larger size, relatively contain a large quantity of deleterious gases which come out very slowly when under the action of the vacuum pumps, it is preferable that clamps be used which have first been carbonized and subjected in vacua to heat sufficient to produce a high degree of incandescence.

3721 When such are used, a very small amount of sugar applied to the ends of the fibers serves by its carbonization to bind them securely together.

The carbons made of the other materials set forth have enlarged ends made upon them, for affording a large and certain connection with the clamps as set forth. For their carbonization a flask constructed in either of the following methods is used. These several forms are unitary in principle, in that they confine and support the material during its carbonization, preventing any distortion, while at the same time provision is made for contraction, and they differ only slightly in the details by which these results are attained.

In one form a plate is provided with a groove or recess of the shape and size desired for the carbon. At one end of the groove is a recess, just large enough to receive one of the enlarged ends of the strip, a pin being used to secure that end therein.

At the other end of the groove is an elongated recess, whose excess of length is equal to the contraction of the material during carbonization, in which rests the other end of the filament to which may be attached or on which may be placed a small weight to keep it straight. During the carbonization this end is drawn up in its elongated recess, the other end remaining fixed. In another form a groove or recess is made of the elliptical form desired with recesses at the ends just sufficient to admit of the enlarged ends of the filament placed sideways therein. The top or apex of the groove is enlarged in this case, one boundary edge being upon a curve equal to the length of the uncarbonized material, while the other is of the

length and shape desired by the filament after carbonization. In another form a recess is cut in a plate of the form desired for the carbon, but of a size that will accommodate the uncarbonized material. In the recess fits and slides a plate, slightly smaller than the recess, so that when the plate is laid in the recess, a groove is left sufficient in size to just receive the filament. Upon
3722 the outer edge of the recess, and at the proper points are
made side recesses just large enough to receive the enlarged ends of the filament. The filament is laid in the groove formed between the recess and its plate, the enlarged ends laying in the recesses provided therefor, weight being laid on the latter to confine them therein. During carbonization, as these ends are fixed, contraction draws down the bow portion, which carries the plate with it, the upper portion of the — preserving the shape of the material.

These plans may be better understood by reference to Figs. 18, 19, 20, 21, 22, 23, 24, 25 and 26, in which Figs. 18, 21, 24 and 25, are plan views of carbonizing plates, unitary in principle, but differing slightly in detail. Figs. 20 and 23, are an edge and side view respectively, of a slip or filament ready for carbonization. Figs. 19, 22, 26 and 27, are details more fully hereinafter referred to. A is the nickel plate in which is cut the groove A of the shape desired for the finished carbon, and of a depth sufficient to receive the slip or filament S.

The coefficient of contraction of the fibre is determined by experiment, and the length of the groove is made equal to the length desired for the finished carbon, plus the contraction of the material during the process of carbonization. In figure 18 this extra length is at one end of the groove, enlarged at one end into a small chamber, just sufficient to receive one of the enlarged ends *c*, of the filament which is secured therein by a pin *e*. A small wedge *f* may also be placed in the chamber to assist in keeping the enlarged end in shape, the pin *e* passing through *c* and *f*. The other end of the groove *a*, is made into a long chamber *b*, whose length is equal to or greater than the amount of contraction, in length of filament in carbonization, upon the free end of the slip or filament the clamp *d* is secured.

3723 The plate A with the slip or filament secured in position as described, is covered by a smooth plate, or a series may be used, piled one upon another, the smooth under surface of one forming the cover to the one underneath.

They are then placed in a suitable nick*le* case, and on being subjected to the first low heat, carbonization and contraction proceed evenly and equally throughout each slip or filament, the contraction drawing up the loose end in the chamber *b*, until at the conclusion of the process the end *d* is exactly opposite *c*. The cases and plates used are made of nickel, as no other metal stands the high heat necessary in the final stage of carbonization.

In figure 21, the groove *a* is shown, formed into a chamber *a* at the bow of the horseshoe. In this case the slip S is laid flatways in the groove, the ends *e c* fitting into chambers at the end of the groove upon which weights *o* are laid.

By this means the ends are held in position during carbonization, while the contraction is from *x* to *x* during the process. Figure 44 shows the same construction and method of operation as in figure 18 except that while in figure 18, the slip is placed edgewise in the groove, in figure 24 it is placed flat or sideways in the groove. In figure 25 the plate A is formed with a chamber, in which slides a plate *c* smaller than the chamber by the size of the filament or strip, so that when the plate *C* is placed in the chamber, a groove shall be left in which is placed in the filament or strip its ends *c c* resting in chambers fitted for them, and held in place therein by weights *g g* laid thereon in chambers made therefor. As the filament is thus fastened at the ends as carbonization proceeds, the ensuring contraction pulls the bow towards the ends forcing the plate *C* towards the end B of A.

In all these plans, however, the filament is kept under strain during carbonization with one or more points fixed against moving,
and the contraction proceeds against the strain which con-
3724 stantly keeps the filament against or in contact with a former,
preserving its shape and obviating any risk of warping or
twisting. In all, provision is made for keeping flat, and in their proper relative position, the enlarged ends of the carbon.

It is also essential that they should be carbonized evenly and equally throughout their entire mass.

This may be accomplished by a furnace of the following description: Preferably a nickel flask is used, composed of two parts, a base plate provided with numerous legs, so as to support the same, and permit the heat to reach the bottom, and a case or box which sets thereon. A series of plates, constructed as before described, is laid upon the bottom, so as to form a pile, and the box or case placed thereon, its edges resting upon the bottom.

The flask is then placed in an oven of a size sufficient to leave a space on every side of the flask. The oven is provided with a top in which is a peep-hole having a removable cover for inspection of the interior. A pipe connected to a source of supply of any gaseous combustible passes around the oven in several branches, inlet pipes therefrom carrying the gas, in as many places as necessary, to the interior of the oven for consumption there.

A pipe connected to a suitable air blast passes around the oven in the same manner from which lead branch pipes; one passing into each inlet pipe of the gas supply so that air under suitable pressure is mingled with the gas at the point of combustion furnishing the proper blast for ensuring the necessary high degree of heat. The gas and air pipes are furnished with proper valves so that the relative supply of each may be regulated. By this means the supply may be so regulated that at first the flask is subjected to a comparatively moderate heat only which is then gradually brought up to the highest degree necessary. The carrying into effect of this
part of the invention may be more clearly understood by
3725 reference to Figs. 28, 29 and 30, of which Fig. 28 is a view of
a carbonizing plate grooved to receive a filament. Fig. 29 is
a perspective view of a series of the plates in the carbonizing flask.

Fig. 30 is a perspective view of the carbonizing oven. In these figures A is a carbonizing plate grooved to receive a filament and to have it secured therein.

The carbonizing flask is composed of two portions *B* and *C*. B is a base provided with numerous legs *b b b b* in order to raise it above the bottom of the oven to permit the free passage of heat there around. Upon B is arranged a series of the plates *A*, each containing a filament and over the series is placed a cover *C* securing them all upon the base and within the flask. The flask so filled is placed within the oven *D*, provided with the cover *E*, and exit *e* for the escape of the products of combustion being provided. A peep-hole may be provided, which is closed by cover F through which the condition of the flask may be observed. A pipe *G* connected to a source of supply of any gaseous fluid passes around the oven in several branches, inlet branches *g g*, therefrom conveying the gas in as many places as necessary to the interior of the oven for consumption.

H is an air tube connected with a suitable blast and passing around the oven in the same manner as *G*, from which lead branch pipes, *h h h*, one passing into each branch inlet *g*, so that air under pressure is mingled with the gas at the point of combustion, furnishing a supply of air for proper combustion and insuring the necessary high degree of heat. Both *G* and *H* are provided with ordinary stop-cocks or valves by which the supply of either air or gas absolutely or relatively to each other may be regulated. The oven, *D*, is of such a size that when the flask is placed in position therein, there is a space on every side between the flask and the oven. The flask filled with plates and filaments is placed in the oven and the fire kindled by lighting the gas. By means of the valve, before mentioned, the supply of fuel may be so regulated that 3726 at first the flask is subjected to a moderate heat which may be gradually brought up to the required point. The blast ensures a high degree of heat directed immediately upon the flask and evenly distributed thereon. When heated for a sufficient time the gas is turned off and the flask may be allowed to cool down in the oven. During the process carbonization there is sometimes danger that the material under treatment may be oxydized to such an extent as to interfere with proper carbonization. This oxydation is due to the oxygen in the air present in the flask and to the oxygen eliminatsd from the wood itself at the commencement of the process. If desired to prevent this an auxiliary tube may be used passing into the flask through which is introduced therein prior to firing and during the burning an atmosphere of hydrogen or of some hydrocarbon or of some other element which will take up the oxygen and prevent its action upon the filaments.

In a system of electric lighting such as proposed by me in which separate electric lamps devoid of regulating devices are used at the places of consumption, the entire regulation for all the lamps being performed at the central station, as with water or gas supply, it is essential that a constant electro-motive force or pressure be maintained. And as in such a system the lamps are arranged upon the multiple-arc or derived-circuit system, it is essential that there should be a certain standard resistance in each derived circuit. This has been attained by placing one lamp of such standard resistance in each derived circuit. It is desirable that all lamps used should be of equal lighting value, each giving a certain standard amount of light. This has been attained by giving each a certain definite or standard amount of radiating surface.

Ordinarily this radiating surface has been that with which the standard pressure, or electro-motive force and the standard resistance should give a light equal to sixteen candles. Some-
3727 times, however, it is desirable in some parts of the system to use lamps which each give a much less amount of light, for instance in chandeliers, where it is desirable to divide the total amount of light produced among a larger number of lamps than ordinary; that is, that the light of one, say, standard 16-candle lamp be divided between two, three or four lamps each of eight, five and one-third, or four candle power respectively. This result may be attained in the following way: In a derived circuit are placed two lamps, each being carefully provided with an incandescent conductor of one-half the resistance and one-half the radiating surface of the incandescing conductor of the standard lamp of the system. A single circuit-breaker is provided for both lamps in order that both shall be turned off or on simultaneously. When desirable the two lamps may be arranged in one holder, which may form a bracket, or may form a section of a group of lamps, or of a chandelier. This part of the invention is shown in Figs. 31, 32 and 33, wherein Fig. 31 is a diagram showing one standard lamp, and two half lamps in derived circuits from the same main conductors. Fig. 32 is a view of two half lamps arranged in one holder, and Fig. 33 is a diagram showing the connection in such holder.

In these figures, $C\ C_1$ are the main conductors leading to and from any suitable source of electric energy at the central station.

In the multiple arc 1, thereto, is a lamp *A*, of standard resistance and radiating surface. In the multiple arc 2 are the two lamps *B B*, each of which has just one-half the radiating surface and one-half the resistance of *A*. One circuit-breaker, *b*, is provided, controlling the circuit through both lamps, as a consequence with an uniform standard electro-motive force or pressure. Each of these lamps will each give one-half the light which A would give. If it is desired to increase the number the same proportion between the number used and the standard resistance and radiating surface should exist.

3728 For two, three or more lamps a suitable holder, *F*, of insulating material is made, sockets *S* being made therein to each lamp. To each socket metallic conducting plates are placed on opposite sides, as at *c c*, *d d*, for forming contact with metal slips, or pieces, on the necks of the lamps.

The socket may be provided with a plain or screw-threaded aperture *B*, by which it may be attached to the wall as a bracket, or to a framing, so that it may constitute a portion of a group of lamps, or of a chandelier. Upon the socket is a circuit-breaker consisting of a metallic screw *D*, secured in a seat *h*, and which may be turned to infringe upon or be cleared from contact with a metal block *e*.

The conductor *C* passes through $c\ c^1$ to *c*, and the conductor C^1 through *d*, d^1 to the metal seat *h* of the screw *D*. Instead of two lamps, as instanced, any number may be used, care being taken that the resistance of each be a fractional part of the standard resistance of one ordinary lamp, the denominator of the fraction being the number of smaller lamps in the one derived circuit. If more than two are used, the block *e* and screw *D* are placed somewhere in the circuit leading through all the lamps, in order that all may be turned on or off simultaneously, all the divided lamps being used as one standard lamp.

In the lamps generally used in my system and referred to hereinbefore, the light is produced by the incandescence of a conductor in an hermetically sealed vessel, the incandescing conductor being the small carbon now generally designated as the "horseshoe carbon." Such, however, are designed for small lamps, usually fifteen to eighteen candle power, and the conductor required therefore being small is hermetically sealed in glass. When it is desired to produce, on the same principle, a much greater light, say one-hundred-candle power, the conductor thereto must also be much larger.

3729 While I have succeeded satisfactorily in sealing somewhat larger conductors hermetically in the glass it is generally not so effective or desirable a method of passing large conductors into the bulb as where small conductors are used.

Wherefore there seems to be a necessity for some other method which in the case of larger conductors shall pass the conductor into the bulb of the lamp without contact with the glass thereof, and at the same time furnish an effective and lasting hermetical seal.

This I have succeeded in doing by the employment in the lamp of two columns of mercury sustained in tubes attached to the lamp bulb, at ordinary barometric height by the pressure of the atmosphere and serving both as seals to preserve the vacuum in the lamp bulb and as parts of the circuit through the incandescent conductors.

A glass globe or bulb is blown of proper size having an annular opening in its base of a size to admit of the passage into the globe of an insulating base supporting the carbon. After this base is put in the globe the annular opening is closed and two tubes connecting with the interior of the globe are connected hermetically thereto of a length somewhat greater than the barometric column of mercury. From the clamps of the carbons conductors pass one from each clamp into the proper tube. The lower ends of the tubes are placed in proper mercury reservoirs insulated from each other, one reservoir being connected to one pole of the source of electricity, the other to the other pole.

The air being exhausted from the globe the mercury rises in the columns or tubes, forming a seal for the vacuum, and also forming

a circuit to the conductors attached to the clamps. The lamp is supported upon or by a frame whose standards are provided with adjusting screws so that its height may be regulated or the leveling of the stand secured. The part of the invention is shown in detail,
in Fig. 34, which is a view of a lamp embodying this part of
3730 the invention, shortened somewhat in proportion to its height
as indicated in the dotted line. A glass globe or bulb *A*, is blown having an annular opening in its base of a size to admit of the base *a, a,* passing therethrough. The line of this opening is indicated at *i, i.* Upon the top of the bulb is formed a tube, the continuation of the projection, *N*, by which the lamp is attached to the air pump. Upon a suitable base *a, a,* of insulating material are fastened by proper devices, the clamps *b, b,* holding and supporting the horseshoe, *B*, the clamps being connected to metallic conductors e, e^1 ; passing a little distance, say several inches below the base *a, a.* Two glass tubes c, c^1, each of a diameter several times greater than that of e or e_1 ; and several inches longer than a column of mercury supported *in vacuo* by atmospheric pressure are united near their top as at *m*, and their united tops formed into a circle the diameter of or slightly larger than the diameter *i, i,* of the opening in *A*. The base *a, a,* supporting the carbon, and with its attached conductors is introduced into *A*, and the tubes *c, c,* are then secured by sealing at *i, i,* to *A*, the conductor *e*, projecting downwardly into *c* and *e*, into c^1. For supporting the lamp thus formed, a stand is employed consisting of an insulated top *E*, and base E^1 united by metallic standards *F*, F^1, which are connected to the base E_1, by adjustable screw connections g, g^1, so that as circumstances require the top may be raised, lowered or inclined. Upon the metal standards *F, F,* are binding screws whereby conductors 1, 4, to and from the source of electricity are attached. The top *E*, is provided with a central aperture, or it may be annular, permitting the tubes c, c_1, to pass through and below it, while supporting the globe. Upon the base *E*, is located a vessel made of insulating material, not affected by mercury, divided into compartments *D*, D^1, or two separate distinct vessels may be used. The tube *c*, passes into one *D*, to near its bottom, while *c* passes into D^1. A wire, 2, connects *D* and *F*, and a wire, 3,
connects D^1 and F_1. The parts being placed in position as
3731 shown in the figure, the vessels *D*, D_1, are filled with mer-
cury, and the tube continuation of *N*, before mentioned, fastened to the pumps. As the air is exhausted from the bulb the mercury rises in *C*, and C^1. During this operation care must be taken that the compartments *D*, D^1, are kept supplied with mercury, and that upon the completion they are still full. Upon the proper degree of vacuum being attained, the bulb is sealed at *N*, and the tube removed, at this stage the mercury has risen to and remains at *x, x,* the height at which atmospheric pressure sustains a column of mercury *in vacuo*, the mercury contacting with e, e^1, and passing a little distance above their ends.

The column *C*, C^1, should be of such a diameter as to give no greater resistance to the current than does either of the conductors e, e_1, 2 or 3. For high-candle-power incandescent lamps this arrangement makes a very reliable and durable seal, obviating any danger there may be of seal breakage, arising from difference of expansion coefficient likely to exist where large metallic conductor is sealed directly to or in glass.

For such reason, in large lamps, this method may prove preferable to that of sealing direct.

Hitherto, in manufacturing the lamp, the carbon having been prepared from paper, wood or other suitable fibre, was placed in the lamp whose parts are then sealed; the lamp was then exhausted of air, a current being applied during the process of exhaustion, heating the carbon.

Prior to sealing in the lamp, and the process of exhausting the completed lamps, the carbons were not heated, and prior to heating any defects therein could not be discovered. It is practically impossible to produce all the loops or slips of absolute uniformity or homogeneity, or to carbonize all of them absolutely uniform throughout their entire mass.

When heated to redness generally throughout their length,
3732 some show spots either less red or of a brighter red than the
average of the carbons, indicating for the first time faults in
the carbons.

Where there is a bad fault in the carbon a white incandescence appears, determining the life of the lamp, and also affecting its resistance. Such lamps are unfit for use, and the entire cost of their manufacture has proved a loss.

I now propose to furnish a simple and easy method and means of testing the carbons before they are put in the lamp proper, and so prevent defective or unsuitable carbons from being embodied in completed lamps to be only thrown away upon the discovery of the faults, increasing in fact the net cost of the faultless ones.

This is accomplished by a preliminary heating of the carbons *in vacuo*, which by the following means can be cheaply, rapidly and effectually done.

What may be called a temporary lamp is formed of a globe or chamber of proper size, with an aperture at its top of a size sufficient to admit of the passage of a carbon and its supporting base. The neck of the supporting base passes tightly through a soft rubber cork which fits into the aperture in top of the globe. The cork is so sized that its upper side is a little distance below the top edge of the aperture so that when the cork is in position, a chamber is formed on top. On one side of the wall of the aperture is an opening having a tube upon its exterior, the opening being into the chamber referred to as formed above the cork. A mercury reservoir is connected to the opening by a flexible tube. When the cork is put into place the reservoir is elevated, and the mercury flows thence forming a seal over the cork; *per contra*, the reservoir being depressed the mercury flows back into the reservoir barring the cork. The globe is connected to a proper exhaust tube, several Springel drops being simultaneously used, by this means a carbon may be placed in the globe, it sealed and exhausted quickly, and the cur-

rent applied testing the carbon, which standing the test
3733 may be placed in a permanent lamp. Suitable mechanism for
carrying this part of the invention into effect is shown in Fig. 35, which is a sectional view of the preliminary proving or testing lamp, in which Fig. Q is the usual glass carbon support which is sealed to the glass globe in the completed lamp at *r*. *a* is the carbon to be proved, secured thereto in the usual way. *C* is the temporary proving lamp, having at its upper end an aperture sufficiently large to admit the carbon and its support and provided with a soft rubber cork B, through which the neck of the carbon support Q, passes. The cork *B* fits tightly in the aperture, the sealing being further rendered secure by a mercury seal *E*, a mercury reservoir *d*, being elevated when necessary so that the mercury therefrom flows down through a tube *c*, over the top of the cork. From the bottom of the proving lamp *C*, proceeds two tubes, one *n*, connecting with a McLeod gauge. The other tube *b*, leads to and connects with the vacuum apparatus. In operation the carbon to be tested is placed in the proving chamber or lamp *C*, and the mouth hermetically sealed. The stop-cock *x* in tube *b* is then opened giving free communication between the chamber *C* and the vacuum apparatus. When the proper degree of exhaustion is attained, circuit is closed through carbon *a*, heating it to incandescence, causing defects if any to be visible.

If the carbon proves defective it is discarded, the only loss being the labor and material which are small, involved in the manufacture of the carbon, and not as hitherto, the labor and materials which were many times greater necessary to a completed lamp.

It is evident that several carbons may be tested at once in the proving chamber or temporary lamp. One of the objects in giving a very high resistance to the incandescing conductors used in my system of lighting is to attain economy of material in the conductors therefor. The resistance usually given them is suffi-
3734 cient for any desired economy in ordinary thickly settled
localities. For use, however, in sparsely settled neighborhoods as say the outskirts or suburbs of a town or city, it may be desirable to have a lamp by the use of which still greater economy of conductor is attained. In such localities, in order to lessen the number of lights needed in the streets, it may also be desirable to have a lamp by which the volume of light is increased in order that economy in the erection of lamp-posts, etc., may be observed, and it may also be desirable to use lamps in which the volume of light may be increased in other localities.

As there is eventually a limit to the effective life of the carbon used, it seems desirable to so arrange a lamp that the operative life of the lamp may be prolonged beyond the average life of a carbon to the end that the cost of the labor expended in embodying a carbon in a lamp may be reduced.

Both or either of these results are attained in the following way: An enclosing globe is used made and put together in the usual manner in my lamps.

To the inner ends of one of the conductors leading into the lamp is fastened a double clamp, that is, one that is Y-shaped a carbon being fastened to each limb of the Y clamp. At the other end each carbon is fixed in an individual clamp, each clamp having its own conductor leading outside of the lamp. The wires leading out of the lamp and the wires leading from a suitable source of electricity are united at a circuit-controlling device, constructed so that it may close the circuit through either carbon, the circuit through the other remaining open, or it may close the circuit through both, as carbons in a series, or it may close a circuit through each, the circuit through them being derived or multiple arc circuits. This part of the invention is more clearly shown in Fig. 36, in which *A*, is a glass globe and *B*, the supporting neck united at *a*, *b*.

Through the neck *B* passes the conductors 6, 7, 8, which are sealed therein. Upon the inner terminal of 6, is the Y-shape clamp
3735 *D*, in each leg of which is fixed a carbon *e* or *g*. The other
ends of these carbons are in separate clamps *e*, being fastened in the clamp *d*, of conductors 8 and *g*, in clamp d^1 of conductor 7.

The conductors 6 7 and 8, and the circuit conductors 5, 9, are connected to a key E, composed of metal contact points; 1, 2, 3, 4 and anvils *x*, *s*, *z*, as follows: Circuit conductor 5, is connected to point 1, contacting with *x*, and to anvil *s*, on which 2, contacts, while 9, is connected to anvil *z*, with which both 3 and 4 may make contact. Conductor 6, is connected to anvil *x*; 7 to point 4 which contacts with *z*, and 8 to 2, which contacts with *s*, and to 3, which contacts with *z*. If points 1 and 3 be put in contact with their anvils *x*, *z*, circuit is formed, 5^1 via 1, *x*, 6, *D*, *e*, *d*, 8, 3, *z* to 9, the circuit through *g* being open. If 1 and 4 be closed on *x* and *z* the circuit is formed 5 via 6, D, g, d^1, 7, 4, z, to 9, the circuit through *e* being open and g alone in circuit and use. If 2 and 4 be closed on *s* and *z*, the circuit is from 5^1 via *S*, 2, 8, *e*, *D*, *g*, 7, 4, *z*, to 9, and both *e* and g are in one circuit, that is in series.

If 1, 3 and 4 be closed on *x*, *s* and *z*, the circuit is from 5^1 via 1, x, 6 to D, where two paths are formed, the current consequently dividing, one circuit being D, *e*, 8^3, *z* to 9, the other D, g, 7, 4, z, to 9, both carbons being in circuit, but each having its own circuit, which is a derived one, so far as the main circuit is concerned.

When both are use- in multiple arc it is evident that the net resistance of the circuit is one-half the resistance of one, and a certain sized conductor is required.

If both are used in series, the resistance is double that of one, and four times that of the multiple arc, in which case, the conductor may be diminished three-fourths. As the volume of light is that of two ordinary lamps, it is evident that a much less number may be used with the same light-giving result. Thus economy in laying main conductors, and in the erection of lamps is secured.

3736 It is evident that as one carbon only may be used at a time that by so using one only at a time, the life of a manufactured lamp is practically doubled, for where one carbon has reached its effective limit the circuit there through is transferred to the other, thus saving the expence involved in sealing one carbon and its globe, the cost of a globe, and of its exhaustion.

It is evident that while only two carbons are shown, that more may be sealed in one globe, D, being provided with the same number of clamps, and each carbon provided with a separate return wire, for which proper connections are made by enlarging key E, on the principle shown.

It is also evident that E may be provided with lever contacts, instead of the screw contacts used to explain the principle of my invention.

In electric lamps formed by sealing an incandescing conductor hermetically in glass-enclosing globe, there may be danger sometimes that the glass and wire will separate at the point where the conducting wires pass through, and are sealed into the glass globe. This is due to the fact that the conducting wires near the incandescing material become very hot by conduction and that the coefficient of expansion of the glass and wire are so different. In the lamp made on my plan owing to the high resistance of the incandescing material, such small conductors are used that the danger referred to has been of minor or the very least importance. It may be desirable, however, to provide means which reduce the danger to a minimum, while affording at the same time, the necessary support for the very small and delicate conductors and incandescing material.

One part of this invention has for its object the provision of such means which is done as follows:

A small glass bulb is blown of a little larger diameter than the distance apart of the ends of the carbon. Through this globe are passed and sealed therein the conductors leading to the carbon, each conductor being sealed therefore in two places, one contig-
3737 uous to the clamps for receiving and supporting the carbon,
the other seal being almost diametrically opposite. The carbon and clamps being placed in position, this small globe is placed in an aperture left for the purpose in the larger enclosing globe, and sealed thereto at about the meridian line of the smaller bulb. The larger bulb is provided with a tube by which it is attached to the air-exhausting apparatus, and where it is sealed after the vacuum is produced. Connected to this tube is a branch tube leading from the smaller bulb, so that both are simultaneously exhausted. This is shown in detail in Fig. 37, in which A is the glass-enclosing globe formed with the tube a for attachment to the exhausting apparatus. A small bulb B is made attached to the supporting neck C, and formed with a tube b. Through the bulb B the conductors 1, 2 are passed and sealed therein, 1 being sealed at c, c^1, and 2 at e, e. The bulb B is then sealed into A at the lines z, z, and the tube b connected to the tube a, the bulb B practically forming the seal to A. The tube a is then connected to the exhaust apparatus. It is evident that a vacuum is created in both A and B. When a proper degree of exhaustion is reached, the tube b is sealed off at y after which the tube a is sealed off at x, x.

The vacuum in globe A, is thus protected by two sealings of each wire c e and c^1 e^1, to only one set of which is there any danger, c^1 e^1, the other set c e, from its distance from the heated portion of the lamp, never heating sufficiently to be affected.

As very small conductors are used, it is necessary for stability that they be supported near the carbon, which is done at the sealings c^1 c^1, but if either of these, from their proximity to the light is ever so heated as to crack, it will still subserve its functions as a support, while the vacuum is preserved by the seals c e, more distant from the clamps. Sometimes it may be desirable to make a
lamp in which a less permanent seal is used, involving a
3738 less expensive method of sealing, and which may be taken
apart readily for the substitution of a carbon or for other
purposes.

This may be done as follows: Upon a tube, closed at one end, is supported the carbon, the conductors therefrom passing through the tube, and being sealed hermetically in the top thereof. The enclosing globe is made with a neck somewhat larger than the tube, so the carbon may be passed therethrough.

A rubber packing is interposed between the outer walls of the tube and inner walls of the neck securing the two together, the ends of the tube projecting beyond the end of the neck.

This projecting portion of the tube passes through the base of a rubber cup, the base of the neck resting upon the bottom of the interior of the cup. At the top of the cup a rubber packing fills the space between the exterior of the neck and the interior of the cup. The space in the cup is filled with mercury, which is retained in place in the cup by the packing last referred to, forming with the rubber a good seal for any temporary uses. Fig. 38 shows a lamp embodying this portion of the invention. A is the enclosing globe made with a long neck, A_1, through which may be passed the carbon B, attached to the clamps b b, connected to conductors 1, 2, which are sealed in the top of a tube C at c c, the tube C being somewhat smaller than the neck A_1. Around the base of C is a soft rubber plug, D, which fits into the lower part of the neck A, forming a tight joint between the two, supporting — and the carbon in position in A_1, and A F is a socket or cup, through the bottom of which by tight joint passes the end of C, the end of D resting in the cup. At the tap of the cup a washer E of soft rubber fills tightly the space between A_1 and the inner wall of the cup F, the space in the cup being filled with mercury, H, or other suitable liquid.

The lamp so put together is exhausted and then sealed at
3739 a in the usual manner, the combination of the cup F, plugs
or washers D and E, and the mercury H forming a reliable
seal.

Having thus described my invention, what I claim is hereby declared to be as follows:

1st. An incandescing conductor formed of one or more carbonized natural fibres, substantially as set forth.

2d. A carbon clamp for uniting the incandescing and the metallic conductors formed of a carbonizable material, substantially as set forth.

3rd. The method of uniting the incandescing and the metallic conductors, which consists in inserting both in clamps made of carbonizable material and then carbonizing the whole together, substantially as set forth.

4th. The slip of carbonization having enlarged ends formed in one piece and homogeneous therewith upon one edge, or one side and one edge, the remaining edge and side being straight, substantially as set forth.

5th. The method of forming a slip or filament for carbonization consisting in securing a blank in clamps or holders, having the configuration desired for the carbon and shaving or cutting away the superfluous material, substantially as set forth.

6th. A slip or filament for forming on carbonization, the incandescing conductor of an electric light, made of bast, or fibre, like cane and bamboo, substantially as set forth.

7th. A slip or filament for forming by carbonization the incandescing conductor of an electric light, made of a material composed of fibres laying parallel through the length of the slip or filament,
substantially as set forth.

3740 8th. A slip or filament for carbonization, provided with
slots or holes in its enlarged ends for holding it in the carbonizer and for passage of the clamping screws when placed in a lamp, substantially as set forth.

9th. The combination of the shaving knife, the block *C*, and means for moving it, and the adjustable limiting screws, substantially as set forth.

10th. The clamp formed of two portions, one being provided with offsets or shoulders, forming the bottom of slots acting as straightedges or *guages* to the slip under treatment, substantially as set forth.

11th. The clamp provided with slotted projections at the ends, for forming the broadened or thickened ends of the slip and the slots therein, substantially as set forth.

12th. The method of forming carbons for electric lamps which consist- in forming the wood into the shape desired for the carbon and then carbonizing the same substantially as described.

13th. The method of forming carbons for electric lamps which consists in cutting or stamping from a veneer a piece of wood with thickened or broadened ends and of the shape desired, and then carbonizing the same substantially as described.

14th. The horseshoe with thickened or broadened ends for attachment to the clamps formed or cut from one piece of wood, substantially as set forth.

15th. The method of forming carbons for electric lamps which consist- in shaping a block of wood as described, then cutting, splitting or shaving into straight pieces adapted for single car-
3741 bons, then bending such pieces into the desired form and
carbonizing in such form, substantially as described.

16th. That block for the manufacture of carbon for electric lamps consisting of the central web and thickened or broadened ends, substantially as set forth.

17th. The method of forming carbon for the incandescing conductors of electric lights, consisting in first cutting or turning a block of wood into the shape of an oval having a broadened portion then carbonizing and then removing a portion of the broadened part, substantially as described.

18th. A carbon horseshoe composed of a filamentary body with broadened ends turned from one piece of wood and then carbonized, substantially as described.

19th. The method of manufacturing carbons for incandescent electric lamps, uniform and regular in shape and carbonization consisting in carbonizing filaments while one or both ends are secured in a certain definite position relatively to the amount of contraction, so that when carbonized and contracted the ends shall be in proper position to each other, substantially as set forth.

20th. The method of manufacturing carbons for incandescent electric lamps, consisting in maintaining the slips or filaments under constant strain, and with one or both ends fixed while in process of carbonization, substantially as set forth.

21st. The method of manufacturing carbons for incandescent electric lamps, consisting in carbonizing the slips or filaments while in grooves, which maintain the shape and provide for contraction during carbonization, substantially as set forth.

3742 22nd. The carbonizing plate provided with a groove for shaping the material, and a chamber or chambers permitting contraction during carbonization, substantially as set forth.

23rd. A carbonizing flask and the plates thereof made of nick*le*, substantially as set forth.

24th. The carbonizing flask or box provided with grooves for the reception of the fibre, substantially as set forth.

25th. The carbonizing oven, consisting of a case and a system of gas and air supply pipes combined substantially as described, and for the purposes set forth.

26th. The combination of a case or -over therefor*s* provided with an inspection aperture and cover, means for supplying gaseous fuel to the interior of the case*d* and means for mingling air under pressure with the fuel, substantially as set forth.

27th. The combination with one derived circuit of a multiple-arc system of two or more lamps, each of a fractional resistance and radiating surface of the *resistance and radiating surface of the* standard lamps of the system, the fraction being the number used, substantially as set forth.

28th. The combination with one socket or holder, and one derived circuit, of one circuit-controller and two or more lamps each of a fractional resistance an- radiating surface of a standard lamp substantially as set forth.

29th. The combination with the incandescing condition of an electric lamp of two fluid columns sustained by atmospheric pressure and forming both a part of the circuit and a hermetical seal to the lamp, substantially as set forth.

3743 30th. The combination with the incandescing conductor and the fluid columns of reservoirs connected to the source of electricity and into which the columns dip for the maintenance of the columns and the completion of the circuit therethrough substantially as set forth.

31st. The combination with an electric lamp of the stand or support therefor, consisting of an insulating base and top connected by adjustable standards substantially as set forth.

32nd. The combination with a globe or chamber of a much larger chamber or reservoir connected to air-exhausting apparatus, which maintains therein a high degree of exhaustion, substantially as set forth.

33rd. The combination of a proving chamber or globe, a mercury reservoir for sealing the same, and exhaust reservoir or chamber and means for exhausting the same, substantially as set forth.

34th. The combination of a globe or chamber a second and much larger globe chamber or reservoir a valved tube connecting them, means for maintaining a high degree of exhaustion in the larger reservoir or chamber, and connected thereto, and gauge for determining the degree of exhaustion, substantially as set forth.

35th. The combination with the globe or chamber of a proving lamp of a mercury reservoir connected to the globe or chamber so that the stopper thereof may at will be covered or not covered by mercury, substantially as set forth.

36th. The method of testing carbons consisting in subjecting them to the action of a current in a temporarily exhausted globe
3744 or receiver, prior to their embodiment in completed lamps, substantially as set forth.

37th. The combination in one electric lamp of two or more incandescing conductors and means for connecting them in the electric circuit; either in series or multiple arcs, substantially as set forth.

38th. The combination in one electric lamp of two or more incandescing conductors, and means for making or breaking an electric circuit through either one, as may be desired, substantially as set forth.

39th. The combination in one electric lamp, of two or more incandescing conductors, and means for completing the circuit through either or through both substantially as set forth.

40th. The combination of contact points 1, 2, 3, 4 anvils X, S, Z, and circuit connections, substantially as set forth.

41st. In an electric lamp, the combination with the enclosing globe or chamber of a second chamber through and into which the conducting wires pass, and are sealed; both chambers being hermetically sealed together and exhausted, substantially as set forth.

42nd. The method of sealing the enclosing globe or chamber of an electric lamp by sealing an auxiliary or secondary globe or chamber in the opening of the first or enclosing globe, substantially as set forth.

43rd. The method of preserving the vacuum in the enclosing globe of an electric lamp, consisting in sealing the conducting wires at two points in a vacuum globe hermetically sealed to the enclosing globe, substantially as set forth.

3749 44th. The combination with the neck of the enclosing globe and the carbon-supporting tube, of a cup containing a liquid receiving the end of the neck of the enclosing globe, and through which passes the carbon-supporting tube and washers or plugs filling the space *bweeetn* the neck and cup and neck and tube substantially as set forth.

THOMAS ALVA EDISON.

New York, N. Y., October 8th, 1880.

Signed in the presence of—
GEO. T. PINCKNEY.
CHAS. H. SMITH.

This is the specification referred to in the affidavit of Thomas Alva Edison hereto annexed. Sworn before me this eighth day of October, A. D., 1880.

GEO. T. PINCKNEY,
Notary Public.

(Here follow diagrams marked pp. 3745, 3746, 3747, & 3748.)

3750

CANADA.

Patent of Invention.

Whereas Thomas Alva Edison of Menlo Park, in the State of New Jersey, one of the United States of America, electrician, has in pursuance of "the patent act of 1872," by his petition to the commissioner of patents, stated that he has invented new and useful improvements in electric lamps, and in carbons or incandescing conductors therefor, and in means for and methods of manufacturing the same, the title whereof is "Edison's electric lamps and means and methods for manufacturing the same," not known or used by others, before his invention thereof, and not being at the time of his application in public use, or on sale for more than one year previous to his said application in Canada, with his consent or allowance, and has elected his domicile at the city of Ottawa, in the Province of Ontario, in Canada. And whereas the said Thomas Alva Edison has also complied with the other requirements of the said act.

The present patent grants to the said Thomas Alva Edison, his executors, administrators and assigns, for the period of fifteen years from the date of these presents, the exclusive right, privilege and liberty of making, constructing and using and vending to others to be used, the said invention of Thomas Alva Edison, and which is called or known by the title or names of "Edison's electric lamp, and means and methods for manufacturing the same," and whereof a short description is as follows:

It consists 1st, in an incandescing conductor, formed by one or more carbonized natural fibres; 2nd, in a carbon clamp for uniting the incandescing and the metallic conductors, formed of a carbonizable material; 3rd, in the method of uniting the incandescing and the metallic conductors, which consists in inserting both in clamps, made of carbonizable material, and then car-
3751 bonizing the whole together; 4th, in the slip for carbonization, having enlarged ends formed in one piece, and

Impt in Electric lamps and in carbons or incandescing conductors therefor and in methods for and means of manufacturing the same No. 11968.

homogeneous therewith upon one edge or one side and one edge, the remaining edge and side being straight; 5th, in the method of forming a slip or filament for carbonization, consisting in securing a blank in clamps or holders, having the configuration desired for the carbon, and shaving or cutting away the superfluous material; 6th, in a slip or filament for forming in carbonization the incandescing conductor of an electric light, made of bast or fibre like cane and bamboo; 7th, in a slip or filament for forming by carbonization the incandescing conductor of an electric light made of a material composed of fibres laying parallel through the length of the slip or filament; 8th, in a slip or filament for carbonization provided with slots or holes in its enlarged ends for holding it in the carbonizer, and for passage of the clamping screws when placed in a lamp; 9th, in the combination of the shaving knife, the block *c* and means for moving it, and the adjustable limiting screw; 10th, in the clamp formed of two portions, one being provided with offsets or shoulders, forming the bottom of slots, acting as straight-edges or gauges to the slip under treatment; 11th, in the clamp provided with slotted projections at the ends, for forming the broadened or thickened ends of the slip, and the slots therein; 12th, in the method of forming carbons for electric lamps, which consists in forming the wood into the shape desired for the carbon, and then carbonizing the same; 13th, in the method of forming carbons for electric lamps which consists in cutting or stamping from a veneer a piece of wood with thickened or broadened ends, and of the shape desired, and then carbonizing the same; 14th, in the horseshoe with thickened or broadened ends for attachments to the clamps formed or cut from one piece of wood; 15th, in the method of forming carbons for electric lamps which consists in shaping a block of wood as described, then cutting, splitting or shaving into
3752 straight pieces adapted for single carbons, then bending such
pieces into the desired form, and carbonizing in such form; 16th, in the block for the manufacture of carbons for electric lamps consisting of the central web and thickened or broadened ends; 17th, in the method of forming carbons for the incandescing conductors of electric lights, consisting in first cutting or turning a block of wood into the shape of an oval, having a broadened portion then carbonizing and then receiving a portion of the broadened part; 18th, in a carbon horseshoe composed of a filamentary body with broadened ends turned from one piece of wood, and then carbonized; 19th, in the method of manufacturing carbons for incandescent electric lamps, uniform and regular in shape, and carbonization, consisting in carbonizing filaments while one or both ends, are secured in a certain definite position, relatively to the amount of contraction, so that when carbonized and contracted, the ends shall be in proper position to each other; 20th, in the method of manufacturing carbons for incandescent electric lamps, consisting in maintaining the slips or filaments under constant strain, and with one or both ends pierced while in process of carbonization; 21st, in the method of manufacturing carbons for incandescent electric lamps, consisting in carbonizing the slips or filaments while

in grooves which maintain the shape and provide for contraction during carbonization; 22nd, in the carbonizing plate provided with a gro-ve for shaping the material, and a chamber or chambers permitting contraction during carbonization; 23rd, in a carbonizing flask and the plates thereof made of nick*le*; 24th, in the carbonizing flask or base provided with grooves for the reception of the fibre; 25th, in the carbonizing oven consisting of a case and a system of gas and air supply pipes combined; 26th, in the combination of a case or cover therefor, provided with an inspection aperture and cover, means for supplying gaseous fuel to the interior of the case, and means for mingling an under
pressure with the fuel; 27th, in the combination with
3753 one direct circuit of a multiple or system of two or more
lamps each of a fractional resistance and radiating surface of the standa*a*d lamp of the system, the fraction being the number used; 28th, in the combination *10th* one socket or holder, and one desired circuit of one circuit-controller, and two or more lamps, each of a fractional resistance and radiating surface of a standard lamp; 29th, in the combination with the incandescing conductor of an electric lamp of two fluid columns sustained by atmospheric pressure, and forming both a part of the circuit and a hermetical seal to the lamp; 30th, in the combination with the incandescing conductor and the fluid columns or reservoirs connected to the source of electricity, and into which the columns dip for the maintenance of the columns, and the completion of the circuit therethrough; 31st, in the combination with an electric lamp of the stand or support therefor consisting of an insulating base and top connected by adjustable standards; 32nd, in the combination with a globe or chamber of a much larger chamber or reservoir connected to an air-exhausting apparatus which maintains therein a high degree of exhaustion; 33rd, in the combination of a proving chamber or globe, a mercury reservoir for sealing the same, and exhaust reservoir or chamber and means for exhausting the same; 34th, in the combination of a globe or chamber, a second and much larger globe, chamber or reservoir, a valved tube connecting them, means for maintaining a high degree of exhaustion; in the larger reservoir or chamber and connected thereto and a gauge for determining the degree of exhaustion; 35th, in the combination with the globe or chamber of a proving lamp of a mercury reservoir connected to the globe or chamber, so that the stopper thereof may at will be covered or not covered by mercury; 36th, in the method of testing carbons consisting in subjecting them to the action of a current in a temporarily exhausted globe or receiver, prior to their embodiment in
completed lamps; 37th, in the combination in one electric
3754 lamp of two or more incandescing conductors, and means for
connecting them in the electric circuit, either in series or multiple arcs; 38th, in the combination in one electric lamp, of two or more incandescing conductors, and means for making or breaking an electric circuit through either one, as may be desired; 39th, in the combination in one electric lamp, of two or more incandescing conductors, and means for completing the circuit through either

or through both; 40th, in the combination of contact points 1, 2, 3, 4, anvils X, S, Z and circuit connections; 41st, in an electric lamp, the combination with the enclosing globe or chamber of a second chamber through and into which the conducting wires pass and are sealed, both chambers being hermetically sealed together and exhausted; 42nd, in the method of sealing the enclosing globe or chamber of an electric lamp, by sealing an auxiliary or secondary globe or chamber in the opening of the first or enclosing globe; 43rd, in the method of preserving the vacuum in the enclosing globe of an electric lamp, consisting in sealing the conducting wires at two points in a vacuum globe hermetically sealed to the enclosing globe; 44th, in the combination with the neck of the enclosing globe and the carbon-supporting tube of a cup containing a liquid receiving the end of the neck of the enclosing globe, and through which passes the carbon-supporting tube, and washers or plugs, filling the space between the neck and cup and the neck and tube.

But for fuller detail of the invention, reference must be had to the specification and drawings, one duplicate whereof is hereunto annexed, and forms an essential part of this patent.

Provided, that the grant hereby made is subject to adjudication before any court of competent jurisdiction. And further, that this patent is subject to the condition that the same and all the rights and privileges hereby granted shall cease and determine and the
patent shall be null and void at the end of two years from
3755 the date hereof, unless the patentee, his executors, administrators or his assignee or assignees, shall within that period commenced, and shall after such commencement continuously carry on in Canada, the construction or manufacture of the invention hereby patented in such manner that any person desiring to use it, may obtain it, or cause it to be made for him at a reasonable price, at some manufactory or establishment for making or constructing it in Canada.

And further that this patent shall be void if, after the expiration of twelve months from the granting hereof, the patentee, his executors or administrators, or his assignee or assignees, for a whole or a part of his interest in the patent, imports, or causes to be imported into Canada, the invention for which the patent is granted.

In testimony whereof, the Honorable Mackenzie Bowel, one of the Queen's privy counsel for Canada, has hereunto signed his name, and the seal of the patent office has been hereunto affixed at the city of Ottawa, in the Dominion of Canada, this eleventh day of November, in the year of our Lord one thousand eight hundred and eighty.

M. BOWELL.

Countersigned,
J. C. TACHE,
Deputy Commissioner.

OTTAWA, *October* 31*st*, 1882.

The patentee having adduced proof that he has been, for reasons beyond his control, prevented from carrying on the manu-

3756 facture of his invention within the two years mentioned in section 28 of the patent, October of 1872, further delay of one year is granted to him. As witness the seal of the patent office hereunto affixed.

J. A. CAMBIE,
Acting Deputy Commissioner.

(Endorsed: Canada, patent of invention in favor of Thomas Alva Edison, for "Edison's electric lamp and means and method for manufacturing the same." Issued on the 11th day of November, 1880, and registered under No. 11968 in the patent office of Ottawa.) J. C. Tache, deputy commissioner.

CONSOLIDATED ELECTRIC LIGHT COMPANY
vs.
THE EDISON ELECTRIC LIGHT COMPANY and THOMAS A. EDISON.

Memorandum of agreement between Wm. E. Sawyer, of the first part, and Albon Man, of the second part.

The party of the first part has made certain inventions and obtained certain patents having reference to the distribution, regulation, production and use of electricity, and especially its use for electric lighting and the forms of burners or lamps, and the 3758 media menstrum or bath, in which light is produced to prevent oxidation, combustion and transference, and is engaged in experiments in these matters to render the same practical, has agreed to sell and convey to the party of the second part fifty-five one-hundredths parts of all his said inventions and patents and discoveries of and concerning the use, distribution, regulation and production of electric currents, especially as relating to electric lighting and all other matters and things affecting the same, for the sum of $2,500, to be paid to the party of the second part within two months as he may require it; he to procure all necessary patents at his own expense; Man to have ten days to complete his arrangements for associates with him, and $150 to be paid to Sawyer meantime for experiment under the agreement with and between these parties dated Feb'y 15, 1878. When all is completed and signed, Sawyer to go on with his experiments and take out his patents, and whenever Man and his associates are ready, a joint stock company to be formed and all inventions and patents to be assigned to it and the stock to go, $\frac{55}{100}$ to Man and his associates, and $\frac{45}{100}$ to Sawyer.

This has no reference to Sawyer's patent electric engine or telegraphs, but does to and includes inventions and discoveries made in aid of electric lighting or other uses of electricity under the experiments above referred to.

Dated March 19, 1878.

3759 COMPLAINANT'S EXHIBIT NO. 28.

Agreement between Sawyer and Man of May 11, 1878. *T. G., Ex.*

United States Circuit Court, Southern District of New York.

THE CONSOLIDATED ELECTRIC LIGHT CO.
vs.
THE EDISON ELECTRIC LIGHT CO. and THOMAS A. EDISON.

Received for record April 4, 1882, and recorded in Liber A 28, page 118, of Transfers of Patents.

In testimony whereof I have caused the seal of the Patent Office to be hereunto affixed.

E. M. MARBLE,
Commissioner.

NEW YORK, *May* 11, 1878.

Whereas, on the 19th day of March, 1878, an agreement was made between the parties hereto, to which reference for particulars is hereby made; and

Whereas, contrary to the expectations of the parties, the plans originally proposed by the party of the first part did not prove practically successful, and the party of the second part then came in and made certain suggestions which were generally adopted, and has, from time to time, made suggestions in relation to the subject-matters of said agreement, which have been adopted, and through which suggestions it is believed that success has been achieved; and

3760 Whereas, the parties hereto are unable to distinguish which of them is the author of different parts of the inventions hereinafter referred to:

Therefore, it is hereby agreed by and between William Edward Sawyer, party of the first part, and Albon Man, party of the second part, in modification of their previous agreement, as follows:

That instead of the letters patent being taken out in the name of the party of the first part solely, it shall be taken out in the names of both parties hereto, and the interest to be held by said parties in the same shall be to the party of the first part $\frac{45}{100}$ and to the party of the second part $\frac{55}{100}$. In other respects the agreement of March 18, 1878, referred to, shall stand, except that the party of the second part is considered to have accepted, and does hereby accept the inventions mentioned in said agreement and those inventions jointly made by himself and the party of the first part, to wit, $\frac{55}{100}$ of the same, for the sum of $2,500, of which sum the party of the first part hereby acknowledges the receipt of $1,372.75; the balance, viz., $1,127.25, to be paid to the party of the first part, from time to time, as he may call for the same, to cover the expenses of letters patent about to be applied for in the United States, and to meet his personal expenses.

Certain inventions, covered by letters patent of the United States, as follows: "Electric engineering and lighting apparatus and system," No. 194,111, dated August 14, 1877; "electric candles," No. 194,500, dated Aug. 21, 1877; "electric apparatus," No. 194,563, dated Aug. 28, 1877; and "electric engineering and lighting system," No. 196,834, dated Nov. 6, 1877; having been assigned to the extent of $\frac{3}{5}$ thereof to James Flanagan, and the party of the first part claiming that he has the right, as he stated at the time of making the agreement of March 19th, to withdraw the same from the said Flanagan and obtain a reassignment thereof
3761 within one year from about the 15th of February last, the party
of the first part hereby agrees to assign to the party of the second part the remaining $\frac{2}{5}$ of said patents, which he now holds, and within the time limited by this agreement with said Flanagan, to redeem from him the other $\frac{3}{5}$, and assign the same to the company to be formed by the party of the second part for the purpose of holding and operating under all the patents obtained and to be obtained, which are referred to in this agreement and in the agreement of March 19th, 1878.

The inventions herein referred to, which are to be jointly patented by the parties herein, are to be considered as though they had been the sole inventions of the party of the first part under the agreement of March 19th, 1878, and a joint stock company is to be formed and all the patents obtained and to be obtained, as proposed in said agreement, are to be assigned to the said company when formed, including the $\frac{2}{5}$ interest in the four Flanagan patents hereinbefore enumerated and agreed to be assigned to the party of the second part, and the stock of the company is to be distributed as set forth in said agreement.

The joint inventions of the parties hereto being at present as follows:

Electric lamp,
Regulator for electric lights, and
Electric lighting system,

and other apparatus and inventions now under consideration. It is hereby agreed that the party of the first part shall devote his time and attention exclusively to perfecting the same and to the procurement of United States letters patent upon the same, the expenses of procuring said patents to be borne by him; but after the proposed company is formed, which shall be with all reasonable dispatch 3762 after the joint patent on the lamp is obtained, the company is to bear the expense of all new patents and new inventions.

And the said Sawyer hereby agrees to assign to said company any rights remaining to him in any of his telegraphic inventions, in so far as their application to the purposes of electric lighting is concerned.

W. E. SAWYER.
ALBON MAN.

Witness:
P. M. STRATTON.

3763 COMPLAINANT'S EXHIBIT No. 30, EDISON'S CANADIAN PATENT. Dec. 17, 1888.

Department of agriculture, patent office.

OTTAWA, CANADA, *Aug.* 7, 1885.

Certified to be true and correct copies of the original petition and oath remaining on record in the office of Thomas Alva Edison, relating to his application for a patent, and on which patent was granted to the said Thomas Alva Edison, bearing date the tenth day of January, 1880, for "improvement in electric lamps and in the method of manufacturing the same," and that the said petition and oath were filed in this office December 19th, 1879.

As witness the seal of the patent office hereto affixed.

A. J. CAMBIE,
Acting Deputy Commissioner of Patents.

Petition.

To the commissioner of patents, Ottawa:

The petition of Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician, showeth:

That he has invented new and useful improvements on electric lamps and in the method of manufacturing the same, not known or used by others before his invention thereof, and not being in public use or on sale for more than one year previous to this application in Canada, with his consent and allowance as such inventor, the title or name whereof is—

3764 "Edison's electric lamp."

Your petitioner therefore prays that a patent may be granted to him for the said invention; and, for purpose of the patent act of 1872, your petitioner elects his domicile in the city of Ottawa, Province of Ontario, Canada.

And your petitioner hereby appoints L. W. Serrell, of New York, N. Y., or his associate, L. J. Conrsolles, of Ottawa, Canada, his attorney, with full powers of substitution and revocation, to prosecute and present application for patent, to sign the drawings, to receive the patent, and to transact all business in the patent office connected therewith.

Signed at Menlo Park, N. J., this 8th day of December, 1879.

(Signed) THOMAS A. EDISON.

In the presence of—
(Signed) S. L. GRIFFIN.

3765 *Oath.*

UNITED STATES OF AMERICA,
State of New Jersey, County of Middlesex, } *ss:*

I, Thomas Alva Edison, of Menlo Park, in the county of Middlesex, and State of New Jersey, United States of America, make oath and swear that I verily believe that I am the first inventor of new and useful improvements on electric lamps, and in the method of manufacturing the same described and claimed in the annexed specifications, and for which I solicit a patent by my petition, dated December 8th, 1879.

And I further make oath that the several allegations contained in said petition are respectively true and correct.

THOMAS A. EDISON.

Sworn before me, at Menlo Park, New Jersey, this eighth day of December, 1879.

[SEAL.] S. L. GRIFFIN,
Notary Public.

Certified that the annexed is a true copy of a patent registered in the patent office, under number 10791, granted to Thomas Alva Edison, and bearing date the tenth day of January, 1880, for Edison's electric lamp, with true copies of the specification and drawings remaining on record in this office, duplicate copies of which were attached to the patent above mentioned together with certificate No. 89, dated October 13th, 1883, of the payment of the fee for a further term of ten years.

3766 Department of agriculture, patent office.

OTTAWA, CANADA, *July* 31*st*, 1885.

[L. S.] As witness the seal of the patent office, hereto affixed.

A. J. CAMBIE,
Acting Deputy Commissioner of Patents.

To all whom it may concern:

Be it known that I, Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician, have invented an improvement in electric lamps, and in the method of manufacturing the same, of which the following is a specification.

In a former application made by me for letters patent in Canada, an improvement in electric lamps is set forth, wherein a filament of carbon is enclosed in a glass bulb, and the atmosphere removed as nearly as possible, and the carbon is brought to an incandescence by an electric current to form the lamp.

My present invention relates to an improvement in the process of manufacturing the carbon filament and in the means for securing the same to the conductors.

I make use of paper of the desired thickness as free as possible from foreign substances or adulterations, and for this purpose I prefer and use "bristol-board." With suitable instruments, such as a punch and die, I cut out a narrow strip of this paper, preferably in the form of an elliptical bow or an arc of a circle, the ends of the strip being by preference wider than the other portions.

A number of these pieces of paper are laid flatwise in the bottom of a mold, preferably of wrought iron, and there is laid on them a light weight in the form of a flat piece of gas-retort carbon or other
device that will not be distorted by the heat. If several of
3767 these are laid one on the other in the mold, a piece of tissue
paper is interposed between each one and the next.

A cover is used to close the mold, and the mold is raised very gradually to a temperature of about six hundred degrees Fahr. This allows the volatile portions of the paper to pass away, and at the same time the mold retains the paper in its proper shape, and the paper is prevented from curling up or becoming distorted as it would be likely to do if the heat was applied suddenly, or the light weight dispensed with.

The mold is now placed in a furnace and heated almost to a white heat and then removed and allowed to cool gradually. The carbon filaments will be found to be smaller than the card-board blanks and to be sufficiently strong and flexible for handling. The ends of the carbon are to be secured to the metallic conductors in any convenient manner.

The carbon filaments prepared as aforesaid are very uniform in their resistance to the electric current, and I make them thin and of a sufficient length to offer a great resistance to the passage of the current.

The clamps that connect the conductors to the ends do not require to be pressed with much force on the carbon, because the resistance to the passage of the current between the clamps and the carbon will be less than the resistance of the carbon filaments, hence but little heat will be developed at the clamps.

In ordinary electric lamps the large carbons do not offer much resistance to the electric current, and unless the clamps are very firmly pressed upon the carbon, the current meets with considerable resistance at the clamps, and hence heat is developed at such clamps.

The clamps that I prefer are made of a steel spring tipped
3769 at the ends with platina or similar metal; the spring is bent
into a circle or bow, and the ends crossed and turned back towards each other similar in shape to the figure 8, with the opening for the carbon between the spring ends at the upper part, the object of this shape is that the pressure of the clamps on the carbon may be increased by the expansion of the spring by the heat of the

lamp, instead of being lessened as it would be, if the wire was only bent into a single bow.

The spring clamps are connected to the platina or similar conducting wires by clips, and the platina wires pass through the glass of the globe or bulb that contains the lamp, the air is to be exhausted from the bulb by any suitable means, and it is preferable to exhaust said air as perfectly as possible, say to the one-eight hundred thousandth of an atmosphere.

The lamps are suspended or supported in any convenient manner, and the electric current from a magneto-electric machine, or other source of electricity is passed through the lamp, and brings the carbon filament to a high incandescence, and the lamp is very durable, and a large number of such lamps can be placed in the electric circuit in multiple arc, or otherwise as desired.

(Here follows diagram marked p. 3768.)

In the drawing—

Fig. 1 is a vertical section of the lamp complete.

Fig. 2 is a side view in larger size of the clamping device.

Fig. 3 is a section at the line *x x* in still larger size.

Fig. 4 is the wire forming one of the clamps before it is bent up to shape.

Fig. 5 is the paper blank before it is carbonized, and

Fig. 6 is a section of the box.

3770 The blank *a* is cut out of paper material such as "bristol-board," in the proper shape, the form shown in Fig. 5 is preferred, the same is laid in the metal mold *b*, and when several are laid one on the other, pieces of thin paper are introduced between. The weight *d* is laid on these; it is to be heavy enough to prevent the paper curling up under the action of the heat, but it allows the paper to contract as the volatile matters are expelled by the heat. This weight *d* is of gas-retort carbon. The cover *e* is placed on the mold and secured, and the mold is heated as before described. The carbon filament *i* forms the lamp when rendered incandescent by the electric current passed through it. The clamp is made of the wire *h* at the ends of which are tips or small rivets *r* of platina or similar material. The wire is bent up and crossed as shown so as to act as a spring in clamping the end of the carbon filament that is placed within such clamp *x*. The wire is attached to a small stock *o* into which the conducting wire *t* passes and is clamped.

The conductors for the two ends of the carbon are inserted into the glass, and the latter intimately melted around them, the carbon and clamps are connected to the wires and the parts introduced within the neck of the bulb *m*, and the glass melted at *r*, the air is exhausted from the globe by the tube *k*, that passes away as shown by dotted lines, and the tube melted together while the vacuum is maintained.

The lamp is ready for the conductors to be attached to it, and the carbon is rendered incandescent by the current that passes through

the same. It is durable as there is nothing to combine with the carbon and it is substantially indestructible.

I claim as my invention—

First. The manufacture of carbons for electric lights from paper.

3771 Second. The method herein specified of manufacturing carbons for electric lights, consisting in exposing the filament of paper to the action of heat in a mold to drive off the volative portions, and carbonize the paper, substantially as set forth.

Third. A carbon for electric light made a filament with the ends broader for the clamping devices that connect the conductors.

Fourth. The clamp for the carbon of an electric lamp composed of a bow or elliptical spring with the ends crossing each other and receiving between them the carbon substantially set forth.

THOMAS A. EDISON.

Menlo Park, N. J., December 8th, 1879.

Signed in the presence of—
EDWIN M. FOX.
S. L. GRIFFIN.

This is the specification referred to in the affidavit of Thomas Alva Edison, hereto annexed, sworn before me this eighth day of December, A. D. 1879.

S. L. GRIFFIN,
Notary Public.

3772 DOMINION OF CANADA, PATENT OFFICE.

This is to certify that the Edison Electric Light Company, the holder of patent No. 10791, granted to Thomas Alva Edison, for alleged new and useful improvements on electric lamps, and in the method of manufacturing the same, bearing date the tenth day of January, one thousand eight hundred and eighty, has paid to the commissioner of patents on the 4th day of May, 1883, the sum of forty dollars, being the fee required for the further term of ten years, to commence and be computed on and from the tenth day of January, one thousand eight hundred and eighty-five, as provided by section 17 of the patent act of 1872, amended by the act of 1883.

In testimony whereof I have hereunto set my hand and caused the seal of the patent office to be hereunto affixed, at the [L. S.] city of Ottawa, in the Dominion of Canada, this thirteenth day of October, in the year of our Lord one thousand eight hundred and eighty-three.

J. H. POPE,
Commissioner of Patents.

Countersigned:
A. J. CAMBIE,
Acting Deputy Commissioner.

3773 46 VICTORIA.

CHAP. 19.

An act to amend the patent act of 1872.—(Assented to 25th May, 1883.)

Her majesty, by and with the advice and consent of the senate and house of commons of Canada, enacts as follows:

1. Section seventeen of "the patent act of 1872," is hereby repealed, and the following is substituted therefor:

"17. The term limited for the duration of every patent of invention issued by the patent office shall be fifteen years; but at the time of the application therefor it shall be at the option of the applicant to pay the full fee required for the term of fifteen years, or the partial fee required for the term of five years, or the partial fee required for the term of ten years. In case a partial fee only is paid the proportion of the fee paid shall be stated in the patent, and the patent shall, notwithstanding anything therein or in this act contained, cease at the end of the term for which the partial fee has been paid, unless at or before the expiration of the said term the holder of the patent pays the fee required for the further term of five or ten years, and takes out from the patent office a certificate of such payment (in the form which may be from time to — adopted) to be attached to and to refer to the patent, and under the signature of the commissioner, or, in case of his absence, another member of the privy council; and in case such second payment, together with the first payment, makes up only the fee required for ten years, then the patent shall, notwithstanding anything therein or in this act contained, cease at the end of the term of ten years, unless at or before the expiration of such term the holder thereof pays the further fee required for the remaining five years, making up the full term of fifteen years, and takes out a like certificate
3774 in respect thereof. Every patent heretofore issued by the patent office in respect of which the fee required for the whole or for any unexpired portion of the term of fifteen years, has been duly paid according to the provisions of the now existing law in that behalf, has been and shall be deemed to have been issued for the term of fifteen years, subject, in case a partial fee only has been paid, to cease on the same conditions on which patents hereafter issued are to cease under the operation of this section."

3775 CANADA.

Patent of Invention.

10791.

Whereas, Thomas Alva Edison, of Menlo Park, in the State of New Jersey, one of the United States of America, electrician, has, in pursuance of "the patent act of 1882," by his petition to the commissioner of patents, stated that he has invented new and useful improvements on electric lamps, and in the method of manufacturing the same, the title or name whereof is "Edison's electric lamp," not known or used by others, before his invention thereof, and not being, at time of his application, in public use, or on sale for more than one year previous to his said application, in Canada, with his consent or allowance, and has elected his domicile at the city of Ottawa, in the Province of Ontario, in Canada. And whereas the said Thomas Alva Edison has also complied with the other requirements of the said act:

The present patent grants to the said Thomas Alva Edison, his executors, administrators and assigns, for the period of five years from the date of these presents, the exclusive right, privilege, and liberty of making, constructing and using and vending to others, to be used the said invention of Thomas Alva Edison, and which is called or known by the title or name of "Edison's electric lamp," and whereof a short description is as follows:

It consists 1st in the manufacture of carbons for electric lights from papers; 2nd in the methods of manufacturing carbons for electric lights, consisting in exposing the filament of paper to the action of heat in a mold to drive off the volatile portions, and carbonize the paper; 3d in a carbon for electric lights made as a filament with the ends broader for the clamping devices that 3776 connect the conductors; 4th in the clamp for the carbon of an electric lamp composed of a bow or elliptical spring, with the ends crossing each other and receiving between them the carbon.

But for fuller detail of the invention, reference must be had to the specification and drawing, one duplicate whereof is hereto annexed, and forms an essential part of this patent.

Provided, that the grant hereby made is subject to adjudication before any court of competent jurisdiction. And, further, that this patent is subject to the condition that the same and all the right and privileges hereby granted, shall cease and determine, and the patent shall be null and void at the end of two years from the date hereof unless the patentee, his executors, administrators, or his assignee or assignees, shall within that period have commenced; and shall after such commencement continuously carry on in Canada, the construction or manufacture of the invention hereby patented in such manner that any person desiring to use it, may obtain it, or cause it to be made for him at a reasonable price, at some manufactory or establishment for making or constructing it in Canada.

And further that this patent shall be void if, after the expiration of twelve months from the granting hereof, the patentee, his executors or administrators, or his assignee or assignees, for a whole or part of his interest, in the patent, imports, or causes to be imported into Canada, the invention for which this patent is granted.

In testimony whereof, the Honorable John Henry Pope, commissioner of patents, has hereunto signed his name, and the [L. S.] seal of the patent office has been hereunto affixed, at the city of Ottawa, in the Dominion of Canada, this tenth day of

3777 January, in the year of our Lord one thousand eight hundred and eighty.

J. H. POPE.

Countersigned:
J. C. TACHE,
Deputy Commissioner.

Certificate No. 89, of the payment of the fee for a further term of ten years hereunto annexed.

A. J. CAMBIE,
Acting Deputy Commissioner.

Endorsed: Canada, patent of invention in favor of Thomas Alva Edison, for "Edison's electric lamp," issued on the 10th day of January, 1880, and registered under No. 10791 in the patent office at Ottawa. J. C. Tache, deputy commissioner.

3778 DEFENDANT'S EXHIBIT "INTERFERENCE STIPULATION." John H. Kitchen, Examiner.

The complainant, by its counsel, hereby stipulates and consents that the defendant may introduce and file in evidence, at or before the closing of its proofs in this suit, and as a part of said proofs, the deposition of any witness examined in the interference (Sawyer & Man *vs.* Edison), with the right on the part of either party to recall any such witness for further examination or cross-examination, and also that defendant may introduce and file in evidence in this suit any exhibits contained in said interference record. Such depositions of witnesses to have same force and effect as if the witnesses had been regularly called, sworn and examined herein, and such exhibits to have same force and effect as originals properly proven, introduced and filed in this suit, subject to objection as to competency and materiality.

This stipulation to be without prejudice to the claim of the complainant that it has already well and sufficiently introduced the entire interference record in evidence, and that the same is now a legal part of the complainant's case herein.

Dated Mar. 14, 1889.

THOMAS B. KERR,
For Compl't.
H. D. DONNELLY, *For Def't.*

3779 NEW YORK, *March 21st*, 1889.

Met pursuant to adjournment.

Present, same counsel as before.

Pursuant to stipulation between counsel for the respective parties dated March 14th, 1889, the defendant offers and files in evidence, in behalf of the defendant, the following depositions and exhibits from the interference record of Sawyer and Man *vs.* Edison, to wit:

I. Depositions of Martin N. Force, Edward H. Johnson, two depositions of John Kruesi, depositions of Francis R. Upton, Stephen

D. Field, T. B. Stillman, William Sawyer, James A. Russell, James D. Potter and James E. O'Keefe.

II. The following exhibits, of which the following is a list, are offered and filed in evidence, to wit:

(1) Edison Exhibit No. 1, sketch referred to in answer 16 of Edison.

(2) Edison Exhibit No. 3, referred to in answer 26 of Edison.

(3) First incandescent lamp, referred to in answer 27 of Edison.

(4) Edison Exhibit No. 4, referred to in answer 29 of Edison.

(5) Edison's Exhibit No. 5, referred to in answer 29 of Edison.

(6) Edison's commercial incandescent electric lamp, referred to in answer 33 of Edison.

(7) Edison's Exhibit No. 6, referred to in answer 39 of Edison.

(8) Edison's Exhibit No. 7, referred to in answer 42 of Edison.

(9) Edison's Exhibit No. 8, referred to in answer 60 of Edison.

(10) Edison's Exhibit No. 9, put in by Sawyer and Man, X Q. 173 of Edison.

3780 (11) Batch of patents put in on Edison's behalf after X Q. 373, as follows viz:

Letters patent of Thomas A. Edison No. 224,339, dated Feb'y 10th, 1880; 227,227, dated May 4th, 1880; 227,228, dated May 4th, 1880; 227,229, dated May 4th, 1880; 223,898, dated January 27th, 1880; also specification of English patent of Thomas A. Edison, No. 2402 June 17th, 1879; also letters patent 205,144 of Sawyer & Man dated June 18th, 1878; 210,152 of Sawyer & Man, dated November 19th, 1878; 210,809 of Sawyer & Man dated December 10th, 1878; 219,771 of Wm. E. Sawyer, dated Sept. 16th, 1879; 211,262 of Sawyer & Man dated January 7th, 1879; 229,335 of Sawyer & Man dated June 29th, 1880; 227,118 of Albon Man dated May 4th, 1880.

(12) Edison Exhibits No. 10, Upton article in Scribner's.

(13) Edison's Exhibit 11, referred to in Upton's answer 31.

(14) Edison's Exhibit 12, referred to in Kruesi's answer 47.

(15) Edison's Exhibit 13, referred to in Edison's answer 379.

(16) Edison's Exhibit 14, referred to in Batchelor's answer 7.

(17) Edison's Exhibit 15, referred to in Batchelor's answer 28.

(18) Edison Exhibit Nos. 23 and 24 referred to in Stillman's answer 14.

(19) Edison's Exhibit No. 25, referred to in Stillman's answer 16, being a copy of Edison's Exhibit 23 published in N. Y. "Sun," January 5th, 1880.

III. Also all other exhibits referred to in the depositions of Edison, Batchellor, Force, Johnson, Kruesi, Upton, Stillman, Sawyer, Russell, Potter, Field and O'Keefe.

3781 IV. The defendant further offers in evidence the following stipulation entered into between counsel for the parties to the said interference on the 11th day of October, 1882, of which the following is a copy, the defendant's "N. Y. Herald and Sawyer Book Stipulation." The following is the stipulation referred to, viz:

In Interference—SAWYER AND MAN
vs.
EDISON.
} Paper Carbons for Incandescent Electric Lamps.

Present: George W. Dyer, counsel for Edison, and Amos Broadnax, counsel for Sawyer and Man.

Parties met, pursuant to agreement, at the office of Amos Broadnax, at No. 10 Pine street, 11th October, 1882.

Counsel for Edison, in behalf of Edison, puts in testimony a book entitled Electric Lighting by Incandescence, by William Edward Sawyer, published by D. Van Nostrand, of New York, 1881. The same is marked Edison Exhibit "Sawyer Book."

Book objected to by counsel for Sawyer and Man as incompetent, irrelevant and immaterial, and not evidence in any sense.

Counsel for Edison also puts in evidence copy of the New York "Herald" of December 24, 1879, and the same is marked Edison Exhibit "Herald, December 24, 1879."

Also copy of the New York "Herald" of January 5, 1880; the same is marked Edison Exhibit "Herald, January 5, 1880."

Also copy of New York "Herald" of January 6, 1880; the same is marked Edison Exhibit "Herald, January 6, 1880," 11th October, 1882, J. E. B.

3782 Counsel for Sawyer & Man enters the same objection to the said papers that he entered to said book.

Counsel for Sawyer & Man admits that the book marked Edison Exhibit Sawyer Book, was written and published by William E. Sawyer, one of the parties to this interference, at the date set down in said book, and that letters signed W. E. Sawyer in the "New York Herald" of December, 1879, and January 5 and 6, 1880, were written and published by William E. Sawyer, one of the parties to this interference, at the rates shown in said newspapers; but counsel for Sawyer & Man, nevertheless, reserves his right to urge all legal objections against the said book and said articles in said newspapers, excepting the fact that the book and said articles in said newspapers were written and published by William E. Sawyer; and counsel for Sawyer & Man reserves especially the right to show that William E. Sawyer is not now and never has been a party in interest to this interference; and that at the time he wrote the letters in the newspapers put in evidence he did not own the whole or any part of the invention in controversy, excepting as a mere stockholder in the Electro-Dynamic Light Company; and that at the time he wrote the book in question he had no interest whatever in the inventions; that he was openly hostile to the owners of said inventions, patents and the other patents granted to said Sawyer & Man; that one of his avowed purposes in writing said book was to destroy and injure the patents and inventions theretofore made and obtained by William E. Sawyer and Albon Man, both jointly and severally, meaning so many of them as were then owned by the Electro-Dynamic Light Company, and that the statements in said books in many particulars are false and malicious. And counsel for Sawyer & Man gives notice to counsel for Edison that as he understands the decision of the

Commissioner he may put in rebutting testimony, not only to the book and the newspaper articles, but also to the testimony-in-chief put in on behalf of Mr. Edison, and that if the counsel for Mr. Edison has a different understanding of the Commissioner's de- 3783 cision, then he gives notice that he will move the Commissioner immediately or as soon as he can prepare the necessary papers for leave to put in such testimony and request counsel for Edison to state upon the record whether he agrees with counsel for Sawyer & Man as to his right to put in such rebutting testimony under the decision of the Commissioner in opening his decision.

Counsel for Edison accepts the notice above given, and states that he does not know what construction will be given to the order of the Commissioner in reopening the case.

Counsel for Edison further gives notice that he here closes his testimony.

J. EDGAR BULL,
[SEAL.] *Notary Public, N.Y. Co., N.Y.*

It is stipulated between counsel that Defendant's Exhibit "Batchellor Note Book No. 52," offered in evidence, March 7th, 1889, before question 171 of the deposition of the witness Batchellor be retained in the custody of Mr. Dyer, one of the counsel for the defendant, and that a copy of said book is to be marked in evidence in lieu of the original and with the same force and effect, defendant's counsel agreeing to produce the original at the hearing or at any reasonable time if requested by complainant's counsel.

Adjourned to 3 p. m. at Mr. Dyer's office, 40 Wall street.

3784 MARCH 23D, 1889.

Met pursuant to adjournment.

Counsel for defendant now produces the book which was marked for identification "Defendant's Exhibit A, Feb'y 20, 1889," after answer 3 of the deposition of the witness, George W. Sawyer, and tenders it to the counsel for the complainant for examination if desired, stating that it is not the purpose of the defendant now to offer that book or any part of it in evidence. Counsel for defendant further states that the book was shown for identification to the witness, George W. Sawyer because it was believed to contain good secondary evidence of matters which have since been sufficiently proven by the best evidence, namely, by the original minutes, contained in the original minute book of the Electro Dynamic Light Company, of a meeting and transactions of the board of trustees of said Electro Dynamic Light Company, held March 20th, 1879.

Counsel for defendant, in accordance with the request made by counsel for complainant, as appears of record on the cross-examination of the witness Sharp, hereby offers in evidence the sworn statement of the witness Sharp, referred to during his cross-examination, and the same is marked "Defendant's Exhibit Sharp's Statement."

Counsel for defendant also offers in evidence the following publications in the "Scientific American," viz:

An article entitled "Another New Electric Light," published in the "Scientific American" for November 16th, 1878, at page 304, and the same is marked "Defendant's Exhibit Sawyer-Man Scientific American Article No. 1."

An article entitled "The Sawyer-Man Electric Lamp," published in the "Scientific American" for December 7th, 1878, at pages 351, 354 and 355, and the same is marked "Defendant's Exhibit Sawyer-Man Scientific American Article No. 2."

3785 Two articles entitled respectively "The Sawyer-Man Electric Light" and "A New Form of Carbon," published in the "Scientific American" for March 8th, 1879, at page 145, and the same are marked respectively "Defendant's Exhibit Sawyer-Man Scientific American Article No. 3," and "Defendant's Exhibit Sawyer-Man Scientific American Article No. 4."

Counsel for complainant waives proof of publication and objects to the exhibits as incompetent.

3786 DEFENDANT'S EXHIBIT "ARNOUX-HOCHHAUSEN" LETTER.
J. H. K., Ex.

Arnoux & Hochhausen, electric experts, dynamo-electric machines, for electric lights, electrotyping, gold, silver, nickel, brass, and copper plating, 2 and 4 Howard street, corner Centre street.

NEW YORK, *Jan'y* 9, 1880.

Mr. Chas. A. Cheever.

D'R SIR: The horseshoe lamp which has found its way into your possession, was put in ours on the 22d Dec. last.

We at once recognized it as a lamp which we had seen at the corner of Walker & Elm streets prior to 1st May last. We saw several styles of carbon burners there about the same time. One object of the experiments made, was to obviate the shadows cast by the carbon-holder, & this amongst others was devised.

Should you desire legal attestation of these facts with dates, by advising with our attorneys, we will put them in possession of the same so that they will be able to draw the necessary papers. We refer you to Mess. Knox & Woodward.

Yours very truly, ARNOUX & HOCHHAUSEN.

3787 DEFENDANT'S EXHIBIT BROADNAX-CHEEVER LETTER.
J. H. K., Ex.

Charles A. Cheever.

P. O. box 3592.

5 TRIBUNE BUILDING, NEW YORK, *Jan'y 8th*, 1888.

DEAR SIR: In reply to your question I have to say that some time in November, 1878, I saw in operation an electric lamp at 94 Walker street in the city of New York. The alleged invention of William E. Sawyer & Albon Man fitted up with a U-shaped carbon. I saw the lamp in successful operation there a number of times. It was in all respects the same as the lamp you show me and which is marked A. M. & B.

Very truly yours, &c., AMOS BROADNAX,
97 *Broadway, N. Y.*

Chas. A. Cheever, Tribune building.

3788 CONSOLIDATED CO.
vs.
MCKEESPORT CO.

DEFENDANT'S EXHIBIT MAN-CHEEVER LETTER. APRIL 4, 1889.
W. T. F., S. E.

3 MERCER ST., N. Y. *Dec. 12th,* 1880.

Chas. A. Cheever, Esq.

DEAR SIR: I have received your two notes of 11th inst., enclosing letter from the Patent Office advising Messrs. Baldwin, Hopkins & Peyton of substitution of Mr. Broadnax as attorney in carbon-arch matter. You are quite right in supposing that I had nothing whatever to do with the matter, and that I should if acting in it have taken all measures to avoid the least discourtesy to Mr. Baldwin, who has in all things conducted himself in the matter not only courteously, but efficiently & to my entire satisfaction. You will also permit me to disclaim on the part of the Electro-Dynamic Light Co. and its officers, not only any intentional discourtesy, but also to express to Mr. Baldwin through you the thanks of the company for his efficient and able management of the matter. The fact is, I suppose, that the whole subject-matter has been left to Mr. Broadnax, the attorney. You will, I think, agree with me that Mr. Broadnax is a gentleman who would not intentionally be discourteous to any one. I shall submit your letter to him and I am sure he will be able to make satisfactory explanation; possibly his letters to Mr. Baldwin may have miscarried or he may have failed to see him as he is now in Washington, and some urgency in getting hold of the details of the matter which he could not do in the Patent Office without filing the power of attorney to himself may have driven him to file it before communication with Mr. Baldwin. Of these things I cannot know, but of the desire of a portion of the officers of the company to keep Mr. Baldwin in the case I do not know, and that the matter of keeping him retained has not yet been acted upon by the company, and that Mr. Broadnax
3789 knew this and is not only of himself and naturally opposed to any discourteous action in any case, but would be especially careful to avoid even the appearance of giving offense under these circumstances. I re-enclose the notice of the department to Baldwin dated Dec'r 9th. I shall see you as soon as possible after our meeting of to-morrow.

Very respectfully yours, ALBON MAN.

As I told you the object of the substitution was to have all patent matters under one supervision.

ALBON MAN.

3790 DEFENDANT'S EXHIBIT B, "HERALD" ARTICLE OF JAN'Y 5, 1880. W. T. F., S. E.

EXHIBIT B.

(From the "Herald" of January 5, 1880.)

No. 78 WALKER STREET,
NEW YORK, *January* 4, 1880.

To the editor of the "Herald:"

Notwithstanding the assertion that one of Mr. Edison's electric lamps has been running for 240 hours I still assert, and am prepared to back up my assertion, that Mr. Edison cannot run one of his lamps up to the light of a single gas jet (to be more definite, let us call it 12 candle power) for more than three hours. To be still more definite I offer to Mr. Edison at No. 226 W. 54th street, in this city, an opportunity to prove what he says.

From the private residence in that street wires are run a circuit of a thousand feet. Mr. Edison shall have every facility; he shall use my wires; he shall have my dynamo machine or other generator of electricity he may prefer, and all I ask is that the power of his light shall be measured by a photometer; that once in place it shall not be interfered with; and that a committee of gentlemen, preferably nominated by the editors of the New York press, shall be present to certify to the facts of the test.

Furthermore, I will place one of my lamps side by side with Mr. Edison's; it shall run at a power of 25 candles; it shall outlast the entire forty lamps at Menlo Park, run at the power of 25 candles; my lamp to stand as it is put up, and Mr. Edison to put up a further lamp as fast as the preceding lamp shall have burned out. I am anxious for this test, and if Mr. Edison has really one of his horseshoe lamps 240 hours he will not refuse to accept my offer, for he will be treated with the utmost courtesy and shall have everything his own way. I adhere in every particular to my original challenge to Mr. Edison.

Respectfully, W. E. SAWYER.

3791 CONSOLIDATED E. L. CO.
vs.
McKEESPORT L. CO.

DEFENDANT'S EXHIBIT C, HERALD OF JAN'Y 6, 1880. W. T. F., S. E.

EXHIBIT C.

(From the "Herald" of January 6, 1880.)

Mr. Sawyer's Exhibitorium.

To the editor of the Herald:

Your remarks this morning were both interesting and to the point. A great newspaper as the Herald undoubtedly is, should be impartial. I don't know much about the newspaper business, but I know that much. In all the time I have been working at this problem of electric lighting, I have been working simply and solely with a view to a genuine scientific success. I have made no money out of it. Instead of selling out I have increased my original interest by $19,000; have bought my own stock from those to whom I made a gift of it, at 50 per cent. of its par value. I think I know enough about this business not to make a very great mistake, and am not risking my reputation by any wild challenges.

The Herald is in error in implying that this is my residence, and that in consequence, this is a kind of a family matter. I hunted New York over to find some one who would permit me to use his house for a public exhibition. As may be imagined, it was not an easy thing to do. Allow me to correct. My residence is No. 261 W. 42nd street; my office is No. 78 Walker street, my shop is No. 141 Elm street, the exhibitorium is No. 226 W. 54th street.

W. E. SAWYER.

3792 Defendant's Exhibit Sawyer-Man Scientific American Article No. 1.

(Scientific American, November 16th, 1878.)

Another New Electric Light.

During the past week the Electro-Dynamic Light Company of New York have exhibited an electric light which is, to say the least, very promising. The apparatus employed was the Sawyer-Man electric lamp, the joint invention of William E. Sawyer, a well-known and successful electrical inventor of this city, and Albon Man, of Brooklyn. As we hope soon to lay before our readers a complete description of the *the* lamp, with illustrations of its mechanism, we will merely remark in this connection that the lamp is enclosed in a hermetically sealed globe of glass, filled with nitrogen, and appears to differ from the common mode of exhibiting the electric light in non-supporters of combustion, mainly in the addition of a slender pencil of carbon, which completes the circuit between what would otherwise be the two carbon poles, and by its incandescence furnishes light in the place of the ordinary voltaic arc. An essential feature of the invention is an ingenious device for dividing the current, and for maintaining a constant uniform resistance in the circuit, whether the lamps are on or off. The light exhibited was steady and brilliant.

3793 & 3794 Defendant's Exhibit Sawyer-Man Scientific American Article No. 3.

(Scientific American, March 8th, 1879.)

The Sawyer-Man Electric Light.

It will be remembered that in our issue of December 7th, 1878, we gave illustrations of this novel and promising form of electrical apparatus. Since that date the inventors have been busy with endeavors to perfect the invention, and, on the evening of February 20, a public exhibition of the light was given in this city by the Dynamo-Electric Light Co. Several improvements in details of construction have been made, but no radical changes. The chief improvement is in the bearing of the upper carbon-holder, to allow for expansion; the lamp has also been made slightly taller. The light exhibited was soft, pure and steady, and susceptible of perfect regulation. Any lamp in the circuit could be turned up or down, from a dull glow to brilliant incandescence, without affecting the rest. An important improvement has also been made in the switch.

The dynamo machine used was about half the size of the one previously employed; there were more lights in the circuit, and the illumination was more brilliant and satisfactory. Comparison was made with gas light, and also with the voltaic arc, clearly demonstrating the superiority of light by electric incandescence for ordinary uses. The carbons used in the Sawyer-Man lamp are now proved to be comparatively indestructible. If, however, the lamp should be broken or otherwise injured by accident, it can be as easily and cheaply removed and repaired as an ordinary gas-burner. As regards economy, tests upon a large scale have not yet been feasible. With the power at command, the indications are that the production of light by this system will range between one-fifth and one-half the cost of gas.

3795 DEFENDANT'S EXHIBIT SAWYER-MAN SCIENTIFIC AMERICAN ARTICLE NO. 4.

(Scientific American, March 8th, 1879.)

A New Form of Carbon.

In describing the Sawyer-Man electric light, last December, mention was made of the peculiar carbons employed, the manner of their production being a secret which Mr. Sawyer did not choose at that time to disclose.

We have now been favored with an exhibition of the process, and a very pretty experiment it makes. The carbons in question are about half an inch long, with the diameter of one sixteenth of an inch. Their color is steel gray, and the surface is hard as steel; within the carbon is tolerably soft.

In his earlier experiments, Mr. Sawyer employed as the source of incandescence, slender pencils of gas-retort carbon in an atmosphere of illuminating gas. The carbons were slowly destroyed, but at the same time they took on a superficial deposit, evidently of carbon, but unlike in lustre and hardness any carbon that Mr. Sawyer had seen. Inferring that a more rapid deposit would be made in a denser hydrocarbon, Mr. Sawyer experimented with a great variety of such liquids, finding olive oil most satisfactory. His method is simply to heat the carbon to an extremely high temperature, by passing through it an electric current, while it is immersed in the oil. The best results are obtained by the use of a pencil of willow carbon, upon which an intensely hard deposit of carbon rapidly forms, as the hydrocarbon is decomposed by the heated pencil.

DEFENDANT'S EXHIBIT MORTON SANITARY ENGINEER LETTER, APRIL 24, 1889. W. T. F., S. E.

To the editor of the Sanitary Engineer:

Having a sincere respect for Mr. Edison as an enthusiastic and ingenious investigator, I am sorry to see his name used by writers who evidently are quite ignorant of the subjects about which they treat in a way that will inseparably connect it with discreditable (because false) claims, evidently made in the interest of financial speculators.

No one can more thoroughly appreciate than I do the originality of conception, the indefatigable patience and immense labor which have been involved in the series of experiments, of which a sketch has been given in the "New York Herald" of Sunday, the 21st; but when I see the conclusion of these, which every one acquainted with the subject will recognize as a conspicuous failure, trumpeted as a wonderful success, I have only left before me the two alternative conclusions—that the writer of such matter must either be very ignorant and the victim of deceit or a conscious accomplice in what is nothing less than a fraud upon the public.

Such writing as this, in fact, has the melancholy result of placing Mr. Edison and his electric light in the same category with Mr. Keely and his "water motor," Mr. Payne and his "electric engine," Mr. Garey and his "magnetic motor," and others of the same class.

Against this I protest in behalf of true science and for the sake of Mr. Edison himself, who has done and is doing too much really good work to have his record defaced and his name discredited in the interest of any stock company or individual financiers.

HENRY MORTON.

3797 STEVENS INSTITUTE OF TECHNOLOGY, *December 22d*, 1879.

P. S.—When I say that the achievements described by the "Herald" of Sunday, the 21st, constitute "a conscious failure," I do not, of course, mean that Mr. Edison has not now, as he had a year ago, a lot of electric lamps running at Menlo Park; but that his year's work, starting out with the most confident assertion of an accomplished success, only awaiting granting of patents to be made public, has ended in landing him in an old method repeatedly tried and abandoned by others, and which this description furnishes no reason to believe has received any important improvement in Mr. Edison's hands.

McKEESPORT.

DEFENDANT'S EXHIBIT MORTON SANITARY ENGINEER INTERVIEW, APRIL 26, 1889. W. T. F., S. E.

A Scientific View of it.

(From the "New York Times" of December 28th.)

Prof. Henry Morton, the president of the Stevens Institute of Technology, who is well known for his researches in physics, and whose experiments were a source of unfeigned pleasure and astonishment to Prof. Tyndall, recently sent a communication to the "Sanitary Engineer" protesting against the trumpeting of the result of Edison's experiments in electric lighting as a "wonderful success," when "every one acquainted with the subject" will recognize it as a "conspicuous failure." To this was added the statement that Edison "has done and is doing too much really good work to have his record defaced and his name discredited in the interests of any stock company or individual financiers." Edison, to whose attention this letter was called, was reported in a newspaper yesterday morning as inviting Prof. Morton or any other electrician to visit the Menlo Park laboratory and see the light in practical operation. In conversation with a Times reporter yesterday Prof. Morton said that for several reasons he did not think he would accept Mr. Edison's kind invitation. "What is needed to be learned," said the professor, "is the durability of these new lamps of Mr. Edison's and the actual economy in the conversion of power into light by his arrangement. For example, according to the statement in the 'Sun,' Mr. Edison places his present lamps and machines as yielding him what is equivalent to 10 gas-burners for every horse power. Now, my own experience with the best dynamo-electric machines, such as those of Siemens, Weston, Brush and Maxim, using the ordinary carbon poles, show that we may obtain a light of from 1,200 to 1,600 candles per horse power. Assuming a gas-3799 burner to be equal to from 12 to 16 candles, this would be about 100 burners per horse power. As compared, therefore, with the electric light obtained between carbon poles, Mr. Edison gets only 10 per cent., showing, therefore, precisely that enormous loss in the division of the light which has been alluded to before as one of the standing difficulties in the way of the practical application of such a system as Mr. Edison is working upon. This is taking simply his apparently rough estimate. For any definite and certain conclusions prolonged and careful experiments, entirely under the control of the investigator, are absolutely necessary."

As regards the durability of Prof. Edison's new lamps, Prof. Morton was not at all sanguine. "Lamps," said he, "in all essential respects identical with these described by Mr. Edison, have been in constant experimental use for several years past, with one invariable result, namely, that while the carbon would operate success-

fully for periods varying from a few hours to several days, it has been found utterly impossible to render them reliably permanent. It is, therefore, in my estimation, here also necessary that experiments of some length, likewise under the entire control of the investigator, should be made in order that a decisive conclusion may be reached. With reference to the confident assertions of success which reach me from various quarters, I must fall back upon my experience of a little over a year ago. Every one remembers how, at that time, Mr. Edison read some remarks of mine by the light of his then brilliantly glowing electric light, and pointed to it as a shining refutation. In turning over some old letters a few days since I came across one from a friend of mine, who is a scientific man of high standing, and was at that time on very intimate terms with Mr. Edison. This letter is dated October —, 1878, and in it I am assured that Mr. Edison's lamp is a perfect success, capable of replacing a gas-burner, and that when I see it I shall, no doubt, be charmed with its simplicity and efficiency. When I reflect that this previous complete success has been since abandoned by
3800 Mr. Edison, I feel that a little caution is needed in accepting the enthusiastic conclusions of his friends, even when they are illuminated by the shining electric lamps which occasion them."

"Can you tell me, Professor," asked the reporter, "what are some of the chief difficulties in the way of the success of Mr. Edison's light"?

"Well," Prof. Morton replied, "the first difficulty of all is the production of a lamp which shall be thoroughly reliable, and neither complicated or expensive. All attempts up to the present lamp in this direction are acknowledged to be failures, and, as I have pointed out, there does not seem to be any novelty, such as would authorize us to hope for a better success in the present one. The next difficulty is in the economical production of small lights by electricity. This is what is commonly meant by the phrase, 'Dividing the electric light.' Up to the present time, and including Mr. Edison's latest experiments, it appears that this involves an immense loss of efficiency. Next comes the difficulty of distributing on any large scale the immense electric current which would be needed, and to provide for their equal action at different points under varying conditions of the number of lights used. In reference to this, as far as I judge from the reports, Mr. Edison has been running not over 50 lights in all, while his 80-horse-power engine ought to supply 800 lights. The small number actually in use does not, therefore, develop this problem in any practical way."

"The question of measuring the current," added the Professor, as the reporter turned to leave, "the loss involved from the necessity of running the machinery without a moment's intermission during the entire time that any light is needed—in other words, the absence of any storing capacity in electricity—and various other matters of detail, while less important than the three principal difficulties which I have given you, are, nevertheless, very serious difficulties in the direction of a successful practical application of electricity for general illumination."

3801 (New York Tribune, Nov. 25th, 1880.)

Electric Lamps in Daily Use.

As easily regulated as gas.

The nature of the new incandescent light—Interest shown in it by scientific men—Points in which it differs from other lights.

Professor Henry Morton, of the Stevens Institute, Hoboken, read a paper at the recent meeting of the National Academy of Sciences on the measurement of new forms of electric lamps operating by incandescence, in which he gave the results of a number of experiments made with the new Maxim lamp. These results were unexpected by those members of the academy who are specially interested in electric lights. Professor Wolcott Gibbs, of Cambridge, expressed his astonishment without reserve, and said that no one had dreamed that the light of incandescence could compete with the light of the arc. Professor George F. Parker, of Philadelphia, who has taken an active interest in the subject from the beginning of Mr. Edison's experiments, said that the statements of Professor Morton certainly marked a year of great progress in electric lighting.

The paper by Professor Morton and the comments it called forth have attracted public attention in no small degree to the electric lamp operating by incandescence, and to the claims that are made for it. Numbers of people daily visit the Equitable building, in Broadway, and examine the lights there. The basement hall is lighted by one or two large arc lamps of about 4,000 candle power each. The public has become so familiar with lamps of this nature that they no longer attract attention. The novelty is the small incandescent lamp, no larger than a gas jet, of which about sixty are kept burning day and night in the rooms and vaults of the Mercantile Safe Deposit Company. The handsomely furnished new reading-room of this company is lighted by a number of these lamps arranged like gas jets. Some are placed upon the walls and
3802 some are clustered in a chandelier. In order not to dazzle
the eyes of readers the brilliancy of the lights in this room is reduced, and it is therefore only in the vaults that the lamp shines with its full strength. The light flickers somewhat, but this defect is probably due to some imperfection in the regulator, which controls the dynamo machines furnishing the electric current. The flickering is not at all marked, and one must look twice to detect it, so that the failure to secure perfect steadiness is not regarded as a serious drawback to the incandescent lamp. The great security vaults of the company, the storage vaults and the rooms, including the large offices and halls, are furnished with the electric light. The larger areas are lighted with the arc lamps, while the incandescent lamps make the smaller rooms as bright as if flooded with sunshine. The electric current is furnished from a single Maxim machine, deriving its power from the engines in the Equitable building. This machine is controlled by a regulator which determines

the force of the electric current required. The lamps are so constructed that they can be turned on and off at will, as gas is managed, with the advantage that the lamps light themselves. There is no waste, because when lamps are turned off the regulator causes the machine to furnish a current of proportionately less strength to the remaining lamps. The lamps now used at the Equitable building have been burning day and night for three weeks, without the failure of a lamp or any perceptible change in the light of a lamp.

An Explanation by Professor Morton.

A "Tribune" reporter received from Professor Morton a few days since a clear explanation of the peculiarities of the Maxim lamp. "This incandescent lamp," said he, "differs from other electric lamps in the respect that it starts with a filament or conductor of carbon made in any way. This filament is placed in a glass globe from which the air has been exhausted, and replaced by the vapor
3803 of gasoline. If there is any weak point or thin part in the
carbon filament, when the current is passed through it, this point or part will become hotter than the rest, and will decompose the gasoline so as to deposit carbon in the form known as coal-gas carbon upon that particular spot. When this spot has been built up to an equal conductivity with the rest of the filament, the current of the machine is increased with the effect of seeking out the next weakest point or thinnest part, and repeating the process just described. In this way the filament becomes glazed with gas carbon. The gasoline is then withdrawn from the globe, and the lamp is ready for use.

"The incandescent lamp differs from the Edison lamp in this regard: Mr. Edison makes a carbon filament and this filament must be perfectly uniform at the start. If any one point happens to be a worse conductor than the rest of the carbon, this point becomes more highly heated than any other point, and if the whole filament is run up to the necessary intensity to give a good light, this point is carried beyond its endurance and vaporizes. As Mr. Edison himself says, it bursts and disappears, and the lamp is destroyed. He has no means of remedying this except by extreme care in selecting material so as to make his filament absolutely uniform; he has no method for correction.

"Another important feature in the Maxim lamp is in the nature of this glazing, as it may be called, or plating of gas carbon—a material which has long been known for its remarkable resisting powers. It is not only incombustible, but it is mechanically strong in a notable degree. In attempting to cut it, the best files and steel saws are soon ruined. Lumps of it may be put into a cupola furnace and they will come out practically unchanged. This would seem, therefore, to be a peculiarly fit material to stand the severe strain to which it is subjected in these electric lamps.

"In determining the economy and efficiency of these and other lamps, it is required to know three things: The amount of light they give as compared with the standard candle, which consumes

two grains of spermaceti per minute; the amount of electric
3804 current flowing through the lamp, and the amount of resistance to the electric current present in the lamp. In order to obtain this knowledge the lamp is placed in the instrument, known as the photometer, where the light it gives is accurately measured by a comparison with that of one or two standard candles, and at the same time by appropriate electric instruments, the amount of the current and the resistance in the lamp are measured. These quantities being known, the power expended by the electric current in overcoming the resistance of the lamp can be calculated by a simple formula. And this is an accurate measure of the work done or the valuable energy expended in the lamp. The candle power is, of course, a measure of the light produced, and that lamp is the most economical which for a given amount of work done or energy expended in it will give us the most light. The work done is expressed in foot pounds per minute, whether it be an electric current or any other form of energy. Thus, a current of 3½ webers passing through a resistance of 5½ ohms would do a work in one minute of about 2,700 foot pounds. A horse power, as everybody knows, is equal to 33,000 foot pounds per minute. Therefore, this amount of work is about one-eleventh of a horse power. The lamp in which this amount of force was being developed or converted into light gave at that time a light of 12 candles; and as evidently 11 such lamps might have been operated by a current developing eleven times the energy of the one used, they would have together produced the light of eleven times twelve candles, or 132 candles, and we would then say the efficiency of this lamp was 132 candles per horse power of electric current. The exact amount of mechanical force in a steam engine or the like required to produce an electric current of one-horse power would vary, of course, with the particular dynamo-electric machine employed and with other conditions, and would, of course, always be notably more than the electric current itself represented."

"What, in a word, would you say the Maxim lamp has accomplished?"

3805 "The system of Maxim is the first one in which has been practically solved the problem of producing a moderately small life with a correspondingly small electric current; or, in other words, of utilizing the small portions of a divided current. There is nothing new, of course, in the idea of dividing the electric current; the practised novelty is in the construction of a lamp that enables us to utilize the portions of the current when it has been divided. What I mean may be made plain by an illustration. Let it be supposed that at one time gas was so little understood that it could not be used except when passed through a burner of not less than 100 candle power, and then let it be supposed that somebody discovered a means by which gas became luminous when used as it now is. The person who, under this supposition, brought gas into general use would have accomplished with gas what the incandescent lamp has done in electric lighting."

3806 In the matter of the litigation now pending between Sawyer & Man and the Edison Electric Light Company.

William Sharp, being duly sworn, testified as follows:

By Mr. Tomlinson:

Q. Please state when you first met Mr. Albon Man, or Mr. Wm. E. Sawyer.

A. I knew Mr. Man for some time prior to the experiments of Sawyer & Man on electric lighting; Mr. Sawyer I met for the first time at the shop of Arnoux & Hockhausen, No. 2 Howard street.

Q. Please state in detail what was the first work done by you for either Mr. Sawyer or Mr. Man relating in any way to electric lighting.

A. I was living in Brooklyn and had a lathe and some tools at my house and did work there. The first work that I did for either Sawyer or Man was done at my house in Brooklyn. Mr. Man brought me some glass globes and some blocks of gas-retort carbon, and stated to me that he desired the carbon filed down and a lamp made. I don't now remember in detail just the character of the lamp. I think I made two lamps, but not more than two. I got pieces of metal and made them in the proper size and shape; as nearly as I can now recollect, the lamp contained a globe of glass about six inches long, and about three or four inches in diameter. I made the supports for the carbon of the lamp and they were inserted through the neck of the lamp globe into the lamp and fastened there by nuts and paper washers. I worked the blocks of carbon down until I had got two pieces of carbon, one of about the size and shape shown in No. 1 of the drawing marked "A," the other a strip of carbon of about the size and shape shown in No. 2 of the drawing marked "A." The circular carbon was, I think, an experiment, and I don't think it was ever put in the lamp. The carbon worked down to the shape shown in No 2, was the size and general shape of the carbon I put in the lamp. These lamps were so made that the carbon could be replaced. I gave the lamps to Mr. Man. Mr. Man, while I was 3807 working on these two lamps, at my house, came at least half a dozen times to my house to instruct me in the work, and occasionally helped me to do the work. I should think I was working on these lamps about a month. I have no knowledge whether while I was making these lamps at my house, anybody else was making lamps for them. I did not know that it was a lamp that I was working on until I went to Mr. Man's office to get my money for it, when he asked me if I knew what I had been making and I told him no; he then told me that it was an electric lamp. I am quite confident that I made but two lamps and two pieces of carbon. The carbon was gas-retort carbon which I worked on, as I have said. About a month after I had delivered this lamp, I saw it for the first time in Sawyer's place, at No. 2 Howard street; I saw it lit at intervals, during a month or two, and I understood that occasionally they would light it and show it. I did not understand that they burned it steadily. They would merely run it to incandescence for a few minutes at a time, and it was their custom to replace the carbon.

Q. When next did you work for Sawyer and Man?

A. I entered their employ while they were at No. 2 Howard street, and remained with them after they were at Elm and Walker streets, leaving them, as nearly as I can now recollect, about May, 1879.

Q. During this time were you at their laboratories or shops during the working hours of each day?

A. Yes, sir.

Q. During this period were you familiar with the work that was done at these laboratories?

A. Yes, sir.

Q. And with the various experiments that were conducted?

A. Yes, sir.

Q. Was any attempt made to conceal from you what was being done, or did you have free access through the laboratory, and were you generally familiar with all that was done while you were in their employ?

3808 A. I had the privilege of seeing anything that was going on and am generally familiar with what was done. I am not an electrician, but am an expert mechanic and was largely employed on mechanical work.

Q. What was the general nature of the work in which you were engaged?

A. Chiefly on the mechanical parts of the lamps that were made; I also worked in forming the carbons to the desired size.

Q. During the time that you were employed by them, what was the general type of lamp on which they were experimenting, or making, as nearly as you now remember?

A. The lamp contained a glass globe about eight inches long by about two inches in diameter. The base of the globe, by nuts and washers, was fastened to glass plates; the glass plate and the globe were clamped together by metal rings. The interior part of the lamp was fastened mechanically to the base of the lamp in different ways. The base of the lamp was then surrounded with melted sealing wax; after this was done the base was placed in a metallic shell and filled with beeswax. The interior of the lamp contained a short pencil of carbon; a disk of soapstone or metal separated the illuminating part of the interior from radiators such as are shown in figure 1 of letters patent 205,144. The shape and character of these radiators, however, differed; some being serpentine and some of other shapes.

Q. From the time that you first were regularly employed by them until the time you left them, which, as nearly as you can recollect, as I understand you, was from September, 1878, to May, 1879, how many completed lamps in all were made by them?

A. I should say a couple of dozen; I am sure that not more than fifty were made.

Q. What was the character of carbon usually employed in these lamps as the incandescent conductor?

A. Usually pencils made from gas-retort carbon.

Q. What was the shape and dimensions of these pencils?

3809 A. Straight pencils, about half an inch in length, varying in diameter from three sixty-fourths to one-sixteenth of an inch.

Q. Were these lamps so constructed that they could be taken apart and new pencils of carbon inserted?

A. They were.

Q. Do you know, and if so, state whether it was their habit to take their lamps apart and replace the pencils which were consumed by new pencils of carbon.

A. I do know that it was their habit so to do.

Q. What is the longest period during which you have known one of their lamps to remain at continual incandescence?

A. Not over an hour; certainly not over two.

Q. Do you ever remember to have been told of a lamp remaining incandescent for over that time?

A. No; I do not remember.

Q. If any lamp had remained incandescent for two or three days at a time, or for a week or two, do you not think you would have been likely to have known of it, or have heard of it?

A. I do.

Q. Did you ever know or hear of a lamp remaining at continual incandescence for as long as a day?

A. I never did.

Q. If one had burned as long as that, would you not have been apt to have known or heard of it?

A. I think I should.

Q. During the entire time that you were there did they make any lamp which you would consider a practical lamp? I mean by that, one that could be made and sold commercially, and actually used for purposes of illumination?

A. No, sir; I think their lamps were merely experiments.

Q. Did you ever know of their making any test of the life of their lamps, or keeping any records as to how long the lamps would burn?

A. No; I don't know anything about that.

Q. Did you ever know of their doing any carbonization while they were at Howard, or at Elm and Walker streets? By 3810 carbonization I mean taking some material such as wood, or paper in its natural state, and making it into carbon by the heat of the furnace?

A. No.

Q. If this had been done to any extent, or if carbons thus made had been used to any extent, would you not have been apt to have known of it?

A. I would.

Q. Then, as I understand you, the carbons which were used, so far as your knowledge goes, were carbons purchased by them and reduced mechanically to the desired size?

A. Yes.

Q. Did you ever know or hear of their carbonizing paper, wood or other substances?

A. I never did.

Q. Did you ever know or hear of their using, or trying in their lamps, carbons made from paper?

A. No, sir.

Q. If this had been done would you have been apt to have known of it?

A. I would, probably.

Q. Did you ever know or hear of their carbonizing any fibrous or textile material?

A. I never did.

Q. If they had done so, would you have been apt to have known of it?

A. I think I would.

Q. Do you know of their using or trying any carbons other than gas-retort carbon, and if so, please state the fact as you understand it?

A. I remember their getting what were called willow charcoal; these were what is generally known as artist's crayons. They were filed down to the desired size. These crayons were always treated by putting a shell of carbon on the outside. The willow crayons are the only kind of carbon, other than gas-retort carbon, which I ever knew them to try or use. I remember some carbons called French carbons, such as are used in arc lights, but these I understand to be gas-retort carbons.

Q. In their laboratories did they have extensive apparatus for the conduct of experiments?

3811 A. They had pretty fair tools, but very little chemical apparatus, as I understand it. The shop more resembled a mechanic's workshop.

Q. Do you know whether they had an air pump of any kind?

A. I never saw one, and I don't think they had one. I think that for a short time they had some sort of apparatus for taking the air out of the globes with water; but they used to send their lamps out. Toward the last they had Mr. Stillman come up to the shop; they then had some apparatus to charge the globes with gas.

Q. Did you ever know of their using in any of their lamps an incandescent conductor as long as two or three inches and as fine as a horsehair?

A. No, sir.

Q. If they had ever used such a conductor while you were with them, would you have known of it?

A. I certainly would.

Q. Did you ever know, or hear, of their experimenting in any way with such a conductor?

A. No, sir; I never did.

Q. Had they ever done so, would you have been apt to have known or seen or heard of it?

A. I certainly would.

Q. If they had had any apparatus for the obtaining of a high vacuum, would you have been apt to have known of it?

A. I think I would.

Q. Did you ever know of their having such an apparatus?

A. I never did.

Q. Who, beside yourself, worked at the shops of Sawyer and Man?

A. Principally—Mr. Meyers, young George Sawyer, William E. Sawyer and William Sawyer, Sr.

Q. Did you ever hear of a Mr. Keating?

A. I believe Keating did some work for them before I went with them. I have heard of him and seen him.

Q. Did you ever know of the interior of their lamp being enclosed in a globe entirely of glass?

3812 A. I never did.

Q. Afterwards did you work with Mr. William E. Sawyer when he was in Ansonia?

A. I did.

Q. Did you assist him in his experiments there?

A. Yes, sir.

Q. Do you know of any lamps being made with a circular carbon, such as shown in the drawing of patent 317,676, while you were in New York?

A. Yes, I did work, myself, on a lamp containing such a carbon. I don't think over two such lamps were made. I think the round carbon was too bothersome. They made many more of the other kind of lamp.

Q. You say you worked with Mr. Sawyer after his separation from Mann, at Ansonia?

A. I did.

Q. What kind of lamp was he then at work upon?

A. The feeder lamp.

Q. Do you know whether he considered that type of lamp better than the lamps he had made in New York?

A. I believe he did. I think he considered it a better style of lamp.

Q Did you ever know of his making a lamp at Ansonia that could be considered practical?

A. I never did.

Q. In the lamps made in New York, were they troubled with blackening of the globe of the lamp?

A. They were; the globe would always blacken if they burned them long enough.

Q. When the globe would blacken, was it their habit to take the lamp apart, clean the globe and put in a new carbon?

A. It was.

Q. When was the first you ever heard of paper carbon being tried by Sawyer, or anybody with whom you were connected?

A. Some time after Sawyer had left Ansonia I knew of Mr. William Wallace, Sr., trying to carbonize a piece of paper, but I don't

3813 think it was ever put in a lamp, as far as I know. He tried to carbonize it, I think, between two pieces of iron. I believe he was led to this by the publication of Edison's experiments.

WILLIAM SHARP.

Subscribed and sworn to before me this 17th day of June, 1886.

JOHN C. TOMLINSON,
Notary Public, N. Y. Co.

The above statement was made by Mr. Sharp in the presence of Mr. James A. Russell and Martin R. Winchell and Mr. J. C. Tomlinson, the witness being interrogated by Mr. Tomlinson, and questions and answers being taken by Mr. Winchell in short-hand.

3814 *Collected Works of Sir Humphrey Davy, Vol. II, London,* 1839, *Pages* 211 *to* 213, *Inclusive.*

An account of some experiments of galvanic electricity made in the Theatre of the Royal Institution.

The apparatus employed in these experiments was composed of 150 series of plates of copper and zinc of four inches square and 50 of silver and zinc of the same size. The metals were carefully cemented into four boxes of wood in regular order after the manner adopted by Mr. Cruickshank and the fluid made use of was water combined with about $\frac{1}{100}$ part of its weight in nitric acid.

The shock taken from the batteries by the moistened hands was not so powerful, but that it could be received without any permanently disagreeable effects. Charges were readily communicated by means of them to connected jars and to a battery, but in this case the effects produced by the electricity were much less distinguished than in the case of immediate application.

When the circuit in the batteries was completed by mean- of small knobs of brass the spark perceived was of a dazzling brightness and in apparent diameter at least one-eighth of an inch. It was perceived only at the moment of the test of the metals and it was accompanied by a noise or snap.

When instead of the metals pieces of well-burned charcoal were employed the spark was still larger and of a vivid whiteness and evident combustion was produced, the charcoal remained red hot for some time after the contact and threw off bright coruscations.

Four inches of steel wire $\frac{1}{170}$ of an inch in diameter on being placed in the circuit became intensely white hot at the point of connection and burned with great vividness, being at the same time red throughout the whole of their extent.

3815 Tin, lead and zinc in thin shavings were fused and burned at their points of contact in the circuit with a vivid light and with a loud hissing noise. Zinc gave a blue flame, tin a purplish and lead a yellow flame at the circumference.

When copper leaf was employed it instantly inflamed at the edges with a green light and vivid sparks and became red hot throughout the whole of its diameter when it did not exceed four inches.

Silver leaf gave a vivid light, white in the centre and green towards the outline with red sparks or coruscations. Platinum in thin slips when made to complete the circuit became white hot and entered into fusion and gave scintillations at the edges, but whether any part was converted into oxide could not be accurately determined.

When gold leaf, attached by gum water to white paper was burned by the spark the light was of a bright yellow and the noise comparatively loud; the gold was converted into an oxide of a purplish brown color which firmly adhered to the paper and by regulating the course of the spark by means of the communicating wire letters and figures were traced by the fusion which appeared somewhat transparent when exposed to the light.

When the galvano-electric spark was taken by means of pieces of charcoal barely covered with cotton, the cotton was readily inflamed; whether in its simple state or sprinkled over with resin or sulphur.

Fulminating mercury and gun pipe were deflagrated by means of the communication of charcoal; and hydrogen and the compound inflam-able gases were readily made to burn when simply in contact with the atmosphere and detonated when mixed with oxygen.

A few only of these results have any claim to originality. On the phenomena of the combustion of bodies by galvanism we have been already furnished with many striking experiments by our own country and by the German and French philosophers. And after the path is once discovered, in researches of this kind, to
3816 pursue it requires but little ability or exertion. An account of common facts under new circumstances particularly when they are accompanied by striking phenomena can, however, never be wholly useless and it sometimes gives a novel interest to the subject and tends to awaken curiosity.

3817 *Collected Works of Sir Humphrey Davy, London, 1839, Vol. II, Beginning at Page 214, under the Title:*

Account of some experiments made in the laboratory of the Royal institution relating to the agencies of galvanic electricity in producing heat and in effecting changes in different fluid substances—

Particularly pages 216–'18–'19–'20.

* * * * * * *

3. When two small pieces of well-burned charcoal or a piece of charcoal and a wire were made to complete the circuit in water vivid sparks were perceived, gas was given out very plentifully and the points of the charcoal appeared red hot in the fluid for some time after the contact was made, and as long as this appearance existed elastic fluid was generated with the noise of ebullition. The

sensible phenomena were nearly the same with the volatile and fixed oils, ether and alcohol; and by means of charcoal the sparks could be produced in concentrated and sulphuric and nitric acids, which are among the best of the less perfect conductors.

The gases produced from different fluids by the galvano-electric spark were examined, and as the results were in most cases what might have been expected from theory, the analysis of them was not made with very minute attention.

When water was acted upon by sparks taken from two pieces of charcoal the elastic products evolved were about one-eighth of carbonic acid, one-eighth of oxygen and the remainder an inflammable gas, which required a little more than half its volume of oxygen for its combustion. With gold and charcoal, the gold being on the zinc side, the gas produced appeared to be chiefly a mixture of oxygen and hydrogen, for it diminished $\frac{7}{10}$ by the electric spark.

The gas disengaged from alcohol, the spark being taken by gold
connected with the zinc end and charcoal, was a mixture of
3818 nearly two parts of oxygen and eleven parts of inflammable
gas which appeared to be light hydrocarbonate.

Ether in the same method of operating gave four parts of oxygen and twelve parts of inflammable gas.

From sulphuric acid oxygen and hydrogen was produced very rapidly, the oxygen being more than sufficient for the saturation of the hydrogen by combustion, and the acid became blue.

The gas from nitric acid detonated with great violence by the electric spark and the residuum was oxygen mixed with a little nitrogen.

The products from the acids there is every reason to believe were evolved chiefly in consequence of the decomposition of the water they contained. And in operating upon these substances as well as upon pure water, a portion of the elastic fluid must have been produced at the time of the slightest transmission of the electricity during the momentary interruption of contact. The apparent ignition of the charcoal in the different fluids depended probably in some measure upon its being surrounded at the moment of contact by globules of glass which prevented the heat produced at the points of it from being carried off by the fluid.

When the spark was taken by means of iron wire in phosphorus rendered fluid by heat under a stratum of water, permanent gas was produced from it, but in a quantity too small to be examined after a process that continued an hour. I purpose to repeat the experiment with conductors of dry charcoal.

* * * * * * *

5. As the great quantity of electricity by it circulates through perfect conductors by means of the larger apparatus increases their affinity for oxygen more, perhaps, than any known agent, and as charcoal by means of it can be rendered white hot and kept in constant combustion in oxygen gas or atmospherical air, I thought *that* trying the effects of the electrical ignition of this substance upon muriatic acid gas confined over mercury.

This experiment was made by means of a small glass tube con-
taining a slip of platina hermetically sealed into it and hav-
3819 ing a piece of charcoal attached to its lower extremity; a
communication was effected by means of iron wires and the
charcoal was made white hot by the successive contacts continued for nearly two hours. At the end of this time the muriatic acid gas had diminished a very little in volume; much white matter had formed upon the charcoal, which was not sensibly consumed. When the gas was examined $\frac{3}{4}$ of it were instantly absorbed by water and the remainder proved to be inflammable. The process was repeated three times; and when the spark was most vivid a white cloud was always perceived at the moment of its production. I am inclined to attribute this phenomenon and other phenomena to the deposition of the water held in solution in the gas by the charcoal and the mercury adhering to it; and the white matter was probably muriate of mercury. The acid gases are rapidly absorbed by charcoal, and this substance, when well made, will take up more than thirty times its volume of muriatic acid gas; so that in the process of ignition a part of the water and of the acid must have been acted upon in a very condensed state.

The want of success in this experiment, the results of which are very similar to those obtained by Mr. Wm. Henry in his trials with common electricity, prevented me from carrying on the process upon fluoric acid gas as I had at first intended. Many of the compounds of gases that are decomposed by heated charcoal might probably, however, be classed in a very simple manner by means of the ignition of that substance by galvanic electricity; and this mode of operating may be conveniently applied for ascertaining the relations of the affinities of charcoal for the constituent parts of compound gases at very high temperatures.

Apparatus for Taking the Galvanic Electrical Spark in Fluids and Aeriform Substances.

Fig. 1 represents the apparatus for taking the spark in
3820 fluids. A is a tube graduated to grain measure; C is a
platina wire hermetically sealed into the tube and having a
piece of charcoal attached to its top; B is a movable platina wire having charcoal at its top; the effect is produced by making a contact between the pieces of charcoal. In cases when the fluids are very imperfect conductors the wires may be used without the charcoal.

Fig. 2 represents the apparatus for taking the spark in gases; it is used over mercury. A and B are the connecting platina wires to which the charcoal is fastened, and C is the graduated tube in which the gas is acted upon.

3821 *Collected Works of Sir Humphrey Davy, Vol. IV, London,* 1840, *pp.* 109, 110, 111, 112, 221, 231, 232.

* * * * * * *

Let two platina wires from the extremities of a battery composed of plates of a foot square be plunged into water, the quantity of gas disengaged from the wires will be nearly the same as from an equal number of plates of an inch square; let the fingers of each hand, moistened with water, be applied to the two extremities of the battery a shock will be perceived, nearly the same as if there had been no connection between the wires and the water. Whilst the circuit exists through the human body and through water let a wire attached to a thin slip of charcoal be made to connect the two poles of the battery, the charcoal will become vividly ignited.

* * * * * * *

The first distinct experiment upon the igniting powers of large plates was performed by MM. Fourcroy, Vauquelin and Thenard. But the greatest combination ever constructed for exhibiting the effects of extensive surface was made by Mr. Children; it consists of twenty double plates, four feet by two, of which the whole surfaces are exposed in a wooden trough, in cells covered with cement, to the action of diluted acids. This battery when in full action had no more effect on water or on the human body than one containing an equal number of small plates; but when the circuit was made through metallic wires the phenomena were of the most brilliant kind. A platina wire of $\frac{1}{30}$ of an inch in thickness and 18 inches long placed in the circuit between bars of copper instantly became red-hot, then white-hot; the brilliancy of the light was soon insupportable to the eye, and in a few seconds the metal fused into globules. The other metals were easily fused or dissipated in vapor by this power. Points of charcoal ignited by it produced a light so vivid that even the sunshine compared with it appeared feeble.

3822 * * * * * * *

27. The most powerful combination that exists in each number of alternations *is* combined with extent of surface is that that — constructed by the subscriptions of a few zealous cultivators and patrons of science in the laboratory of the Royal institution. It consists of two hundred instruments connected together in regular order, each composed of ten double plates arranged in cells of porcelain, and containing in each plate thirty-two square inches; so that the whole number of double plates is 2,000, and the whole surface is 128,000 square inches. This battery, when the cells were filled with 60 parts of water mixed with one part of nitric acid and one part of sulphuric acid, afforded a series of brilliant and impressive effects. When pieces of charcoal about an inch long and one-sixth of an inch in diameter were brought near each other (within the thirtieth or fortieth part of an inch) a bright spark was produced, and more than half the volume of charcoal became ignited to whiteness, and by withdrawing the points from each other a constant discharge took place through the heated air in a space equal at least to four inches, producing a most brilliant ascending arch of light, broad and conical in form in the middle. When any substance was introduced into this arch it instantly became ignited; platina melted as readily in it as wax in the flame of a common candle; quartz, the sapphire, magnesia, lime, all entered into fusion;

fragments of diamond and points of charcoal and plumbago rapidly disappeared and seemed to evaporate in it even when the connection was made in a receiver exhausted by the air pump; but there was no evidence of their having previously undergone fusion.

When the communication between the points positively or negatively electrified was made in air rarified in the receiver of the air pump the distance at which the discharge took place increased as the exhaustion was made, and when the atmosphere in the vessel supported only ¼ of an inch of mercury in the barometrical gauge the sparks passed through a space of nearly half an inch,
3823 and by withdrawing the points from each other the discharge
was made through six or seven inches, producing a most beautiful coruscation of purple light, the charcoal became intensely ignited and some platina wire attached to it fused with brilliant scintillations and fell in large globules upon the plate of the pump. All the phenomena of chemical decomposition were produced with intense rapidity by this combination. When the points of charcoal were brought near each other in non-conducting fluids such as oils, ether and oxymuriatic compounds brilliant sparks occurred and elastic matter was rapidly generated; and such was the intensity of the electricity that sparks were produced even in good imperfect conductors such as nitric and sulphuric acids.

V.—*Of Carbon or Charcoal and the Diamond.*

1. The name carbon signifies the pure inflammable part of charcoal, lamp-black and other similar substances. The purest known form in which it can be obtained is by passing oils or spirit of wine through ignited tubes. It even appears as an impalpable black powder; it has no taste or smell; it is a conductor of electricity; it is more than twice as heavy as water. For the common purposes of experiments the charcoal of light wood, such as the alder, that has been exposed to boiling water and afterwards ignited to whiteness is sufficiently pure. Such charcoal, however, rapidly attracts moisture from the atmosphere so as to increase in weight from 12 to 14 per cent. and when dry absorbs several times its volume of any gas to which it may be exposed and it must therefore be employed immediately after ignition and whilst yet warm.

Carbon whether coherent in charcoal or in powder is infusable by any heat that has hitherto been applied. I have exposed it to the powers of intense ignition of different voltaic batteries—that of Mr. Children mentioned on page 109, one of forty double plates of 18 inches square and the battery of 2,000 double plates of four inches both *in vacuo* and in compressed gases on which it had
3824 no power of chemical action. A little hydrogen was given
off from it and it slowly volati-zed in these experiments and the part remaining was much harder than before, so as in one case to scratch glass, and the lustre was greater, but its other properties were unaltered, and there was no appearance of fusion. Its capacity for heat, according to Dr. Crawford, is to that of water as .2631 to 1.

* * * * * * *

Page 231.

12. Plumbago or black lead and anthracite or stone coal are both tolerably pure forms of the carbonaceous element. In plumbago the carbon is united either chemically or mechanically to about $\frac{1}{25}$ of iron; in anthracite with small quantities of earthy matter. In the anthracite of Kilkenny in Ireland, the texture is often fibrous and the substance has all the characters of well-burned charcoal. In flaming coal the carbonaceous element is united to bitumen.

13. Few substances are more important in civilized life than the different forms of carbon; in their various uses they are essential to the comforts and well-being of society and are necessary in almost all the useful arts and manufactures.

The inflammable gases produced by the distillation of pit coal have already been successfully used in manufactories for the purposes of affording light, and the application is at once safe and economical.

In nature the carbonaceous element is still active in an important series of operations; it is evolved in fermentation and combustion in carbonic acid; it is separated from oxygen in the organs of plants, is a principal element in animal structure and is found in different forms in almost all products of organized beings.

3825 *Collected Works of Sir Humphrey Davy, Vol. V, London,* 1840, *pp.* 172, 173.

* * * * * * *

When small pieces of charcoal from the willow that had been intensely ignited are acted upon by voltaic electricity in a Torricellian vacuum every precaution being taken to exclude moisture from the mercury and the charcoal, the results were very different from those occurring in the case of plumbago.

When plumbago was used after the first spark which generally passed through a distance of about $\frac{1}{8}$ of an inch there was no continuation of light without a contact or an approach to the same distance; but from the charcoal a flame seemed to issue of a most brilliant purple and formed as it were a conducting chain of light of nearly an inch in length at the same time that elastic matter was rapidly formed some of which was permanent. After many unsuccessful trials I at length succeeded in collecting the quantity of elastic fluid given out by half a grain of charcoal; the process had been continued nearly half an hour. The quantity of gas amounted to nearly an eighth of a cubical inch; it was inflammable to the electric spark with oxygen gas and four measures of it absorbed three measures of oxygen and produced one measure and a half of carbonic acid. The charcoal in this experiment had become harder at the point and its lustre where it had been heated to whiteness approached to that of the plumbago.

* * * * * * *

Pp. 220, 221, 222.

III.—*Further Inquiries Respecting Carbonaceous Matter.*

On the idea which I have stated that they may consist of the carbonaceous matter combined with a little oxygen I exposed charcoal intensely ignited by voltaic electricity to nitrogen, conceiving it possible that if this body was an oxide containing oxygen
3826 very intimately combined it might part with it in small proportions to carbonaceous matter and give an important result.

The charcoal which had been made with great care was preserved for a quarter of an hour in a state of ignition in which platina instantly fused. It did not appear to change in its visible properties; but a small quantity of black sublimate which proved to be nothing more than finely divided carbonaceous matter collected in an arborescent state upon the platina wire to which the charcoal was attached. The gas had increased in volume $\frac{1}{6}$; but this was owing to the evolution of carburetted inflammable gas from the charcoal; the nitrogen was unchanged in quantity and as far as my examination could go, in quality. The points of the charcoal where the heat had been intense were rather harder than before the experiment.

I have mentioned that charcoal even when strongly ignited is incapable of decomposing corrosive sublimate. When charcoal in a state of ignition is brought in contact with oxymuriatic acid gas the combustion instantly ceases. I electrified two pieces of charcoal in a globe filled with oxymuriatic acid gas which had been introduced after exhaustion of the globe. They were preserved after nearly an hour in intense ignition by the same means that had been employed in the experiment on nitrogen. At first white fumes arose probably principally from the formation of common muriatic acid gas by the action of the hydrogen of charcoal upon the oxymuriatic acid and the combination of the gas so produced with aqueous vapor in the globe; but this effect soon ceased. At the end of the process oxymuriatic acid gas was found unaltered in its properties, copper leaf burned in it with a vivid light. The charcoal did not perceptibly differ from the charcoal that had been exposed to nitrogen. My view in making this experiment was to ascertain whether some new combination of carbonaceous matter with oxygen might not be formed in the process, and I hoped likewise to be able to free charcoal entirely from combined hydrogen and from alkaline and earthy matter supposing they existed in it not fully combined with
3827 oxygen. That hydrogen must have separated in the experiment it is not possible to doubt, and on evaporating the deposit on the sides of the globe, which was in very minute quantity and acted like concentrated muriatic acid, it left a perceptible and saline residuum.

P. 275.

V.—*Some Considerations of Theory Illustrated by New Facts.*

* * * * * * *

Muriatic acid gas, as I have shown and as is further proved by the researches of MM. Gay Lassac and Thenard is a compound of a body unknown in a separate state and water. The water, I believe, cannot be decompounded unless a new combination is formed; thus it is not changed by charcoal ignited in the gas by voltaic electricity; but it is decompounded by all the metals; in these cases hydrogen is elicited in a manner similar to that in which one metal is precipitated by another; the oxygen being found in the new compound.

VII.—*Researches on the Oxymuriatic Acid, Its Nature and Combinations, and on the Elements of the Muriatic Acid, with some Experiments on Sulphur and Phosphorus Made in the Laboratory of the Royal Institution.*

P. 285.

In the second volume of the Memoirs d'Arcueil, MM. Gay Lassac and Thenard have detailed an extensive series of facts upon muriatic acid and oxymuriatic acid. Some of their experiments are similar to those I have detailed in the paper just referred to; others are peculiarly their own and of a very curious kind; their general conclusion is that muriatic acid gas contains about $\frac{1}{4}$ of its weight of water; and that oxymuriatic acid is not decomposable by any substance but hydrogen or such as can form triple combinations with it.

3828 One of the most singular facts that I have observed on this subject, and which I have before referred to, is that charcoal, even when ignited to whiteness in oxymuriatic or muriatic acid gases by the voltaic battery, effects no change in them; if it has been previously freed from hydrogen and moisture by intense ignition *in vacuo.*

3829 *Watt's Dictionary of Chemistry, Vol.* 1, *London*, 1863, *pp.* 759 *and* 760.

Carbon.

Wood charcoal.—Wood consists of carbon, hydrogen and oxygen, the two latter being in the proportion to form water. When heated in the open air it burns completely away with the exception of a small quantity of white ash; but if the supply of air is limited only the more volatile ingredients burn away and a greater part of the carbon remains behind. This is the principle of the process of charcoal-burning as it is practiced in countries where wood is abundant, on the Harz mountains in Germany, for instance. A number of billets of wood are built up vertically in two or three rows into a large conical heap which is covered over with turf or moistened charcoal ash, holes being left at the bottom for

air to get in. A hollow space is also left in the middle of the heap to serve as a flue for the gaseous matters which are evolved. The heap is set on fire by throwing burning pieces of wood into the central opening near the top of which, however, a kind of grate made of billets of wood is placed to prevent the burning fuel from falling at once to the bottom. The cumbustion then proceeds gradually from the top to the bottom and from the centre to the outside of the heap; and as the central portions burn away fresh wood is continually thrown in at the top so as to keep the heat quite full. The appearance of the smoke shows how the combustion is proceeding; when it is going on properly the smoke is thick and white; if it becomes thin and especially if the blue flame appears it is a sign that the wood is burning away too fast; the combustion must then be checked by partially stopping up the holes at the bottom or by heaping fresh ashes on the top and sides, and pressing them down well so as to diminish the draft. As soon as the combustion is completed the heap is completely covered with turf
or ashes and left to cool for two or three days. It is then
3830 taken to pieces and the portions still hot are cooled by
throwing water or sand upon them. The quantity of charcoal thus obtained varies with the manner in which the combustion is conducted. 100 parts of wood yield on the average from 61 to 65 parts by measure or 24 parts by weight of charcoal. When the burning is very carefully conducted the quantity may amount to 70 per cent. by measure.

In England a large quantity of charcoal is obtained in the dry distillation of wood for the preparation of acetic acid. For this purpose the wood is heated to redness in cast-iron cylinders whereupon a number of volatile products are given off, including a large quantity of tarry matter and inflammable spirit called wood spirit or wood naphtha and acetic acid; and in the retorts there remains a quantity of charcoal.

For the manufacture of gunpowder charcoal is sometimes prepared by subjecting wood in iron cylinders to the action of overheated steam (Violette, Ann. Ch. Phys. (3) XXIII, 475.)

Wood charcoal is more or less compact according to the kind of wood from which it is formed. The lighter woods such as willow yield a very porous charcoal, having comparatively little power of conducting heat and electricity; boxwood on the contrary yields a very compact charcoal which is a good conductor of heat and electricity, and is admirably adapted for exhibiting a voltaic light. The density and conducting power of charcoal are greatly increased by exposing it in close vessels to a very high temperature. Charcoal retains the form and to a considerable extent the external structure of the wood so that a horizontal section exhibits distinctly the concentric rings and the traces of the medullary rays. When burned it leaves from 1 to 5 per cent. of ash. According to Berthier 1,000 parts of limewood leave 50 parts of ash; of oak, 25; birch 10; fir 8; hornbeam 26; beach 30.

3831 *Watt's Dictionary of Chemistry, London,* 1875, *Second Supplement.*

Carbon.

P. 255.

Carbon allotropic modifications.—Despretz found several years ago that all kinds of carbon heated in the electric arc of a battery of 500 to 600 Bunsen's elements soften and are ultimately converted into graphite. According to Bettendorf (Arch. Pharm., 2, CXLIV, 79), gas coke may be thus transformed by a battery of only 24 elements. When wood (of box, ash, hornbeam, elder, lilac or cork) or flax, hemp, cotton, paper or silk is placed in a porcelain tube, vapor of carbon sulphide passed over it at or during temperatures till all the air is driven out and the tube then slowly and gradually heated to redness for about an hour, the organic substance is found, after cooling, to be converted into a kind of coke, having the ring of steel, silver, &c., and a great power of conducting heat and electricity. When heated it gradually becomes incandescent throughout its whole mass, without taking fire at any particular part, and cools down as soon as the source of heat is removed; it might perhaps be used to form the carbon cylinders of Bunsen's battery. It exhibits metallic lustre on its surface, is denser than wood charcoal, and does not sensibly absorb gases. A kind of carbon which is a good conductor of heat and electricity, and does not absorb gases, is likewise obtained by strongly heating wood in a crucible filled with charcoal powder. Wood spirit, hydrocarbons, &c., likewise act like carbon sulphide in converting wood into elastic and conducting carbon. The wood spirit suffers decomposition at the same time, whereby the interior of the tube becomes coated with silver white threads of carbon about a centimeter long (Sidot. Compt., Rend. LXX, 605).

3832 "*Mechanic's Magazine,*" *Vol.* 44, *pp.* 312–316, *London,* 1846.

King's patent electric light (letters patent for Scotland, dated November 26, 1845; specification enrolled March 25, 1846).

The nature of this invention (a communication from abroad) is described generally as consisting in "the application of continuous metallic and carbon conductors intensely heated by the passage of a current of electricity to the purposes of illumination. The following details would be nearly in the words of the patentee:

Metallic conductors.—The metal most advantageous for the purpose is that which while it requires very high temperature for its fusion has but a feeble affinity for oxygen and offers a great resistance to the passage of an electric current. Platinum, though not so unfusible *is* iridium, has but little affinity for oxygen and offers a great resistance to the passage of the current; and as it is abundant and easily worked into the required form it is deemed prefer-

able to any other metal. The platinum should be worked into those exceedingly thin sheets known by the name of leaf platinum. This may be accomplished by the ordinary process of the gold-beater; but a more accurate method is to place a piece of platinum foil between two thick plates of rolled copper and reduce the whole to a thin sheet by rolling, when on separating the copper pieces the platinum leaf will be found of uniform thickness in every part. In this way it may be obtained so thin that on holding it before a printed page the letters can be distinguished through it. A strip is to be cut from one of those sheets of a width proportionate to the quantity of the current which with Daniel's cells 20 inches high and three inches in diameter is about ¼ of an inch and of a length proportionate to the intensity which, of course, varies with the number of cells. Great care must be taken to cut the platinum strips of an equal width throughout, and with a clean edge, and if
this is not carefully attended to the strip will be unequally
3833 heated and will be fused in one part before the other parts
have obtained a sufficiently high temperature to produce a brilliant light. Platinum strip is now to be suspended between two forceps in an instrument made for the purpose, one form of which is shown in section —— in the engraving annexed and marked No. 1; A is a square brass bar fixed into the wooden stand C, having a binding screw F attached to its lower end. The two arms E D are attached to sockets which slide on this bar so as to admit of their being placed at different distances from each other. They are both bent at right angles, as seen in the figure, and terminated by bright forceps tipped with platinum. These forceps are closed by the milled screws H I; the arm C has a rod N with a screw cut on it, passing through it, and by means of the two nuts B B working on this rod the arm may be adjusted to any required height and the distance between the forceps thus regulated. The rod passes through the stand and is attached to the binding screw G. The socket K is lined with ivory or some other non-conducting substance so as to prevent any metallic connection between the arm E and the bar; S is the strip of platinum leaf which is first clamped in the upper forceps; the arm E is now adjusted to any required height and the lower forceps are closed so as to clamp the lower end of the strip of platinum. It may now be included in the battery circuit by attaching one of the wires to the binding screw at F and the other to that at G. The current should be one of considerable intensity and the distance between the forceps should be sufficient to prevent the platinum being fused. The distance can be lessened by raising the arm E and shortening the strip of platinum until it attains the highest temperature it will bear without fusing; or the same object may be obtained by increasing the intensity of the current. The glass shade R which serves to screen the platinum from currents of air, dust, &c., may then *may* be placed over the apparatus as seen in figure 1.

Carbon conductors.—When carbon is used, it becomes necessary
on account of the affinity this substance has for oxygen at
3834 high temperature to exclude from it air and moisture. To

accomplish this in the most perfect manner it should be enclosed in a Torricellian vacuum. One form of the apparatus for this purpose is shown in section in the figure No. 2; *a*, is a glass tube similar to those used for barometers except that it has its upper end enlarged into a cy-ndrical bulb and a stout platinum wire sealed in at the top. A small cup for holding mercury is fixed on the top of this wire whose lower end screws in the iron piece *d*, to this piece the forceps *f* are attached and it is connected with a similar piece at *h* by a porcelain rod *i*. The forceps are attached to *h*, and clamped to the lower end of the carbon piece *c* which is its upper end, held by this at *f*; *n* is a copper wire which is fixed into the piece at *h* and extends to the bottom of the tube; the tube is filled with mercury in the same manner as a barometer, the usual precautions being taken to expel the air; its length independent of the bulb should be about thirty inches so that when it is inserted in a cup of mercury a vacuum will be formed in the bulb. The instrument is included in the battery circuit by connecting one of the wires from the battery with the cup fixed on the wire *e* and the other with the wire which passes into the mercury in the cup at the bottom of the tube. The circuit is thus completed by the column of mercury, and when it is depressed in the tube by the formation of vapor of the mercury in the bulb the action is preserved by the copper wire *n*; that form of carbon on the interior of coal-gas retorts which have long been used is well suited for this purpose and it may be worked into the form of either small pencils or thin plates by the aid of the saw and file. As carbon will bear a very high temperature without fusion or volatilization a much more intense light can be produced by this means than by platinum.

When an intermittent light for light-houses is required it may be obtained by breaking the circuit at intervals by clock-work; to effect this one of the wires from the battery is connected with a spring which is made to press on the circumference of a metallic wheel fixed on one of the arbors of the clock having certain
3835 portions of its surface cut away so as to break and close the
circuit at any required intervals. When the apparatus is suitably sealed it may be applied to submarine lighting and also to the lumination of places where it is necessary to guard against the inflammation of highly combustible or explosive compounds; as in powder magazines, mines, &c. When a current is of sufficient intensity two or more lights may be made in the same circuit, care being taken to regulate the power by increasing or diminishing the number of cells—if a voltaic battery is the source of electricity, or the number of armatures of a magneto-electric machine be used—so that the united resistance of the strips of platinum or carbon shall be sufficient to prevent the passage of such a quantity of electricity as would destroy them.

Claim.—"The application of continuous metallic and carbon conductors intensely heated by the passage of a suitably regulated current of electricity to the purposes of illumination as before mentioned."

Note by the Editor.

We fear that the project of lighting by electricity—now a very favored one with ingenious speculators and well deserving, doubtless, of every encouragement—is now likely to be much advanced by the present scheme. Both platinum and carbon have been before proposed to be employed as the illuminating bodies or media and both found objectionable—the former as yielding too feeble a light, and the latter a light which though brilliant is uncertain and, at best, of short duration. We subjoin two paragraphs from our common-place book which may suffice to show not only the want of novelty in Mr. King's imported invention but the point at which the labors of men of science in this department have arrived.

"1845, November 8, M. de la Rive is stated in the Moniteur Industriel to have succeeded in obtaining a brilliant light for lighting mines by the galvanic battery. His pile is composed of
3836 several concentric cylinders of copper or platina separated by
porous cylinders and forming a series of four or five couples. An amalgam of liquid zinc or potassium the positive metal; and a solution of sulphate of copper for copper cylinders and chloruret of platina for platina ones. The difficulties in maintaining a constant light have been overcome by employing small, hollow cylinders of coke similar to those used in Bunsen's pile but smaller and arranged like the wicks of a lamp and rings or discs of metal around these. The electric current passes between the two. The current must be made to pass from the coke cylinder that the particles of carbon which are carried off may fall again by their own weight. The whole is placed in a glass globe which must be hermetically sealed. There is no occasion to form a vacuum in it as the small portion of oxygen is soon absorbed; but it must be carefully excluded from the outer atmosphere. The pile is fitted with two metallic wires—one connecting with the cylinder of charcoal and the other with the metallic conductor."

1845, December 7.—Professor Groves soon after the publication of his nitric-acid battery was struck by the facility and constancy with which the voltaic arc could be obtained by that combination as compared with any previous one and made many attempts to reduce it to practical form for the purposes of illumination with, however, only limited success; charcoal as in M. de la Rive's experiment formed the terminals of the voltaic pile. Sometimes he could keep a constant light for four or five hours but it was never sure; from some unseen defect in the charcoal it would become suddenly extinct; the glass also became dull from carbon vapor which settled upon it; it was costly and not sufficiently portable. There were difficulties which he could not overcome and he proceeded to experimentalize on another method which struck him as likely to be more applicable to lighting mines; he substituted the voltaic ignition of a platinum wire for the disruptive discharge in place of the charcoal arrangement. The light from the platinum is doubtless inferior to

the carbon yet it is too intense for the naked eye to sup-
3837 port and employ sufficient for the miner to work by. His plan was to ignite a coil of platinum wire as near the point of fusion as practicable in a closed vessel of atmospheric air or other gas and by the light of which he states he has experimented and read for hours and the apparatus he used was as follows: At each end of a coil of platinum wire is affixed a copper wire of convenient length the lower ends of which are to be well varnished and inserted either through the bottom of a glass vessel or bent up along its sides and connected to each end of a nitric acid battery; water is then poured into the vessel and another glass inverted over the coil and its supports which the water thus hermetically seals and an ignited wire now gives a steady light without an alteration or inconvenience as long as the battery continues constant—the length of time being of course dependent on the quantity of electrolyte in the battery cells. The spirals of the coil should approximate as near as possible as each aids by its heat that of its neighbor and it should be as long as the battery is capable of igniting to a full incandescence. The helix form offers the advantages that the cooling effects being lessened a much longer wire can be ignited by the same battery; by this increased length of wire the battery fuel is economized while a greater light is afforded; by the increased heat the resistance is still further increased and the consumption still further diminished; so that contrary to the usual result the increment of consumption decreases with the exaltation of effect produced. The very necessity of enclosing the coil in a glass recipient also augments the heat, the light and the resistance. In experiment on the effect of different gases on radiant heat he found by filling the vessel with hydrogen, the coil was not even visible in the dark; an increase of volume by expansion took place from 35 to 43; in carbonic acid cherry red by daylight increased from 35 to 43; in oxygen by daylight 35 to 45; nitrogen the same; and atmospheric air the same as in oxygen. These appear important and satisfactory results, but actual practice on a larger scale can alone test their efficiency.

3838 (The Mining Journal) p. 348.

King's Patent Electrical Light.

SIR: In your last number are some remarks appended to the specification of Mr. King's patent for an electrical light where it appears to me you have overlooked the distinctive feature of this arrangement.

All the early attempts that have been made to effect this important and interesting object were founded on the well-known experiment of producing an arch of flame between two charcoal points forming the termination of the conducting wires of a battery; but they have failed in consequence of the difficulty of rendering the light permanent; for it is found that the substance of one of the points is carried away and deposited on the other which ultimately destroys the essential conditions of success, besides which the light frequently ceases without any apparent cause so that it cannot be depended upon with any degree of certainty even for a few minutes.

Mr. Starr (the inventor of this patented arrangement) has overcome the difficulty by using continuous metallic and carbon conductors sufficiently thin to be intensely heated by the passage of electricity through them. This every electrician will allow, differs essentially from the disruptive discharge taking place through the air as in the experiment with the charcoal points which was performed by Sir Humphrey Davy, and of which M. de la Rive's arrangement is only a slight modification.

The experiment of Professor Grove is without doubt the same in principle as that claimed by the patentee, the only difference (when the platinum is used) being in the form of the conductor which, however, affects the result as regards the quantity of the light produced very considerably. The experiment of Professor Grove was first made public on December 1st, 1845; but Mr. King's patent was sealed for England November 4th of the same year; so that the priority is unquestionable, as is also the novelty of the
3839 principle of obtaining light for the useful purposes from intensely heated continuous conductors. The claim is not for a new substance for producing the electrical light but for a new method. Carbon has long been used for the terminal points between which the light passes, but its application as a conductor itself to be rendered luminous by the passage of the electricity through it is unquestionably new. Respecting the utility of the invention it would at present be premature to offer any remarks, as it must be tried on a scale of magnitude similar to that which will be required for its ultimate application in order to fairly test it. This will very shortly be done as Mr. Starr is at present engaged in fitting up apparatus which will fully demonstrate it.

I may, however, observe that the light produced by the platinum in this arrangement is by no means favorable, for it exceeds in power any light at present used. That from the carbon is still more brilliant than the platinum and is not in the least degree uncertain; nor is there any reason to believe from the experiments already made that any change will take place in its substance, however long it may continue in operation. I hope shortly to be able to communicate definitely the results of these experiments and of others which are about to be made, as they will be found very interesting not only on account of their useful application but as affording very beautiful illustrations of the laws of electrical action and eliciting some new and important facts.

Yours respectfully, WILLIAM WILLIAMS.

3840 DEFENDANT'S EXHIBIT PHILOSOPHICAL TRANSACTIONS, PAPER No. 1. W. T. F., Spec. Ex'r.

Philosophical Transactions of the Royal Society of London for the Year 1809.

Volume 9, Part I. Printed by W. Bulmer & Co., Cleveland road, St. James, London, England. Pages 32 to 38, inclusive.

II.—An account of some experiments performed with a view to ascertain the most advantageous method of constructing a voltaic apparatus for the purposes of chemical research, by John George Children, Esq., F. R. S.

Read November 24, 1808.

The late interesting discoveries by Mr. Davy having shown the high importance of the voltaic battery as an instrument of chemical analysis, it became a desirable object to ascertain that mode of constructing it by which the greatest effect may be produced with the least waste of power and expense.

For this purpose I made a battery on the new method with plates of copper and zinc connected together with leaden straps soldered on the top of each pair of plates; which are 20 in number, and each plate four feet high by two feet wide. The sum of all the surfaces being 92,160 square inches, exclusive of the single plate at each end of the battery. The trough is made of wood with wooden partitions well covered with cement to render them perfectly tight so that no water can flow from one cell to another. The battery was charged with a mixture of three parts fuming nitrous and one part sulphuric acid diluted with thirty parts of water and the quantity used was 120 gallons.

In the presence and with the kind assistance of Messrs. Davy, Allen and Pepys the following experiments were made:

Experiment 1. 18 inches of platina wire of one-thirtieth of an inch were completely fused in about twenty seconds.

3841 Exp. 2. Three feet of the same wire were heated to a bright red, visible by strong daylight.

Exp. 3. Four feet of the same wire were rendered very hot, but not perceptibly red by daylight. In the dark it would probably have bright red throughout.

Exp. 4. Charcoal burnt with intense brilliancy.

Exp. 5. On iron wire of about one-seventieth of an inch diameter the effect was strikingly feeble. It barely fused ten inches and had not power to ignite ten feet.

Exp. 6. Imperfect conductors were next submitted to the action of the battery and barytes mixed with the red oxide of mercury and made into a paste with pipe clay and water was placed in a circuit, but neither on this nor on any other similar substance was the slightest effect produced.

Exp. 7. The gold leaves of the electrometer were not affected.

Exp. 8. When the cuticle was dry no shock was given by this battery, and even though the skin was wet it was scarcely perceptible.

Before I offer any observations on the inferences to be drawn from these experiments I shall mention some others performed for the sake of comparison with the foregoing with an apparatus very different in size and number of plates from the one just described.

This second battery was precisely the Couronne des Tasses of Sig. Volta, consisting of 200 pairs of plates, each about two inches square, placed in half pots of common queensware, and made active by some of the liquor used in exciting the large battery to which was added a fresh portion of sulphuric acid equal to about a quarter of a pint to a gallon.

To state as shortly as possible the effects produced by this battery.

Experiment 1. It decomposed potash and barytes readily.

Exp. 2. It produced the metallization of ammonia with great facility.

Exp. 3. It ignited charcoal vividly.

3842 Exp. 4. It caused considerable divergence of the gold leaves of the electrometer.

Exp. 5. It gave a vivid spark after being in action three hours. At the expiration of twenty-four hours it retained sufficient power to metallize ammonia and continued with gradually decreasing energy to produce the same effect till the end of forty-one hours, when it seemed nearly exhausted.

From the results of the foregoing experiments which though simple and not numerous, I trust are satisfactory, we see Mr. Davy's theory of the mode of action of the voltaic battery confirmed. He says (in his paper on some chemical agencies of electricity, section 9, after having shown the effect of induction to increase the electricity of the opposite plates): "The intensity increases with the number and the quantity with the extent of the series."

That this is so, the effects produced on the platina and iron wires in the first and fifth experiments with the large battery and the subsequent experiments on imperfect conductors with the small apparatus sufficiently proved. The platina wire being a perfect conductor and not liable to be oxydated presents no obstacle to the free passage of the electricities through it, which, from the immense quantities given out from so large a surface evolved on their mutual annihilation heat sufficient to raise the temperature of the platina to the point of fusion.

With the iron wire of one-seventieth of an inch diameter, the effect is very different, which is explained by the low state of the intensity of the electricity (sufficiently proved by its not causing any divergence of the gold leaves of the electrometer), which being opposed in its passage by the thin coat of the oxide formed on the iron wire at the moment the circuit is completed, a very small portion only of it is transmitted through the wire. To the same want of intensity is to be attributed the total inability of the large battery

to decompose the barytes and its general weak action on bodies
which are not perfect conductors. The small battery on the
3843 contrary exerts great power on imperfect conductors, decom-
posing them readily, although its whole surface is more than thirty times less than that of the great battery; but in point of number of plates it consists of nearly ten times as many as the large one. The long-continued action of the small battery proves the utility of having the cells of sufficient capacity to hold a large quantity of liquor by which much trouble of emptying and filling the troughs is avoided, and the action kept up without intermission for a long space of time, a circumstance in many experiments of material consequence. Besides this advantage with very large combinations a certain distance between each pair of plates is absolutely necessary to prevent spontaneous discharges which will otherwise ensue accompanied with vivid flashes of electric light as I have experienced with a battery of 1,250 four-inch plates on the new construction. And here I beg leave to mention an experiment which though not directly in point cannot be considered as foreign to the subject of this paper. It has been urged as one proof of the non-identity of the common electricity and that given out by the voltaic apparatus that in the latter there is no striking distance. That objection, however, must cease. I took a small receiver open at one end, through perforations in the opposite sides of which were placed two wires with platina points well polished. One was fixed by cement to the glass, the other was movable by means of a fine screw through a collar of leathers, and the distances between the points was ascertained by a small micrometer attached. This receiver was inverted over well-dried potash over mercury, and suffered to stand a couple of days to deprive the air it contained as thoroughly as possible of moisture. The 1,250 plates being excited precisely to the same degree as the great battery mentioned in the beginning of this communication, and the little receiver placed in the circuit, I ascertain its striking distance to be one-fiftieth of an inch. That I might be certain that the air in the apparatus had not become a conductor by increase of temperature, I repeated the experiment several times
with fresh cool air and always with the same result; but
3844 perhaps it will be objected that the striking distance was so
small as not to afford a satisfactory refutation of the argument alluded to when it is considered to how very great a distance comparatively the spark of the common electrical machine can pass through air. The answer to this is obvious. Increase the number of the plates and the striking distance will increase, for we see throughout the intensity proportioned to the number, and it probably may be carried to such an extent as even to pass through a thicker plate of air than the common spark. The great similarity of the appearance of the electric light of this battery *in vacuo* and that of the common machine might also be urged as an additional proof of the identity of their nature.

The effect of this large combination on imperfect conductors was, as may be supposed, very great. Of the same platina wire of which the four-feet plates fused eighteen inches, this battery melted but half an inch, though had the effect been in the ratio of their surfaces it should have fused nearly fourteen inches.

The absolute effect of a voltaic apparatus, therefore, seems to be in the compound ratio of the number and size of the plates, the intensity of the electricity being *at* the former, the quantity given out as the latter; consequently regard must be had in its construction to the purposes for which it is designed. For experiments on perfect conductors very large plates are to be preferred, a small number ot wicks will probably be sufficient; but where the resistance of imperfect conductors is to be overcome, the combination must be great, but the size of the plates may be small, but if quantity and intensity be both required, then a large number of large plates will be necessary. For general purposes four inches square will be found to be the most convenient size.

Of the two methods usually employed, that of having the copper and zinc plates joined together only in one point and movable is much better than the old plan of soldering them together through the whole surfaces and cementing them into the troughs, as 3845 by the new construction the apparatus can be more easily cleaned and repaired and double quantity of surface is obtained. For the partitions in the trough glass seems the substance best adapted to secure a perfect insulation; but the best of all will be troughs made entirely of Wedgewood's ware, an idea I believe first suggested by Dr. Babington.

XX.—An account of some experiments with a large voltaic battery by J. G. Children, Esq., F. R. S.

Read June 15, 1815.

In 1809 I presented to the society a short account of some experiments performed with a voltaic battery of unusually large plates, which has been honored by publication in the philosophical tranactions for that year. Since that period I have constructed another of still larger dimensions, the effects of which form the subject of the present communication. The copper and zinc plates of this apparatus are connected together in the usual order by leaden straps; they are six feet long by two feet eight inches broad, each plate presenting thirty-two square feet of surface. All the plates are attached to a strong wooden frame suspended by ropes and pulleys, which, being balanced by counterpoises is easily lowered and lifted so as to immerse the plates in the acid or raise them out of it at pleasure. The first trials of the power of this instrument were made in July, 1813, in the presence of several philosophical friends, but the effects then fell very short of my expectations, arising, as I afterwards found, from a defect in the construction, which has been since remedied and another copper plate added to each member of the series, so that every cell now contains one zinc and two copper plates, and each surface of zinc is opposed to a surface of copper. This was done at the suggestion of Dr. Wollaston and has very considerably increased the power of the battery. From some comparative experiments which I made with a small apparatus 3847 the increase in quantity of electricity thus effected is at least one-half. The cells of the battery are twenty-one in number and their united capacities amount to nine hundred and forty-five gallons. To each pole of the battery a lead pipe about three-quarters of an inch in diameter is attached by solder and the opposite end of each pipe immersed in a basin of mercury (a separate basin for each pipe), by means of which the circuit is completed and a perfect contact ensured. The first experiments I shall mention were made on the comparative facility with which different metals are ignited when placed in the electrical circuit. For this purpose in each experiment two wires of dissimilar metals were taken of equal diameter and length; one end of each was in contact with one of the basins of mercury communicating with the poles of the battery, and the other end bent to an angle and the wires connected continuously by hooking them together. The length of each wire was eight inches and the diameter one-thirtieth of an inch. The battery was moderately excited by a charge of one part acid diluted with forty parts of water.

Exp. 1. A platina and a gold wire being thus connected and introduced into the electrical circuit, the platina was instantly ignited, the gold remained unaffected.

Exp. 2. A similar arrangement of gold and silver wire. The gold was ignited, the silver not.

Exp. 3. The same with gold and copper. No perceptible difference in the state of ignition; both metals were heated red.

Exp. 4. Gold and iron. The iron was ignited; the gold unchanged.

Exp. 5. Platina and iron. The iron ignited instantly at the point of contact next the pole of the battery. Then the platina became ignited through its whole extent. After this the iron became more intensely heated than the platina and the ignition of the latter decreased.

Exp. 6. Platina and zinc. The platina was ignited. The zinc was not, but melted at the point of contact. In a subsequent experiment the zinc did not melt, but the platina ignited as before.

3848 Exp. 7. Zinc and iron. The iron was ignited; the zinc bore the heat without fusing.

Exp. 8. Lead and platina. The lead fused at the point of contact.

Exp. 9. Tin and platina. The tin fused at the point of contact. No ignition of either wire took place in the last two experiments.

Exp. 10. Zinc and silver. The zinc was ignited before it melted. The silver was not ignited.

The results in every case were the same to whichever pole of the battery either wire was presented. I varied these experiments by introducing several alternations of different wires continuously connected into the circuit and obtained in every instance analogous results. Thus:

Exp. 11. Alternations of platina and silver three times repeated; all the platina wires were ignited and none of the silver.

Exp. 12. One zinc wire between two platina; both the platina wires were ignited, the zinc not.

Exp. 13. One iron between two platina. Both the latter first ignited; then the iron, which soon became most heated and fused.

It is unnecessary to enter into a farther detail of these experiments; it will be sufficient to say generally that when wires of several different metals were introduced at once into a circuit the order of their ignition was precisely that of the former experiments. In one experiment with copper and gold, the copper was decidedly most heated.

I feel some difficulty in attempting an explanation of the preceding phenomena, and offer the following conjecture with diffidence. When a perfect communication is established between the poles of the battery, the electricity circulates without producing any visible effect; but if it meet with resistance in its passage it manifests itself by chemical action by the evolution of heat or both. Thus, if a bar of metal be connected with one pole of the battery and its extremity immersed in a basin of mercury connected with the other pole, at the instant the surfaces come in contact heat 3849 and light are evolved, which cease as soon as the bar, if it be of sufficient size, is fairly plunged beneath the surface of the quicksilver. If the circuit be completed by two pieces of charcoal, the evolution of heat and light is permanent as long as their surfaces remain in contact, because that contact can never be so perfect as to oppose no resistances to the electricity; whereas, in the case of the bar of metal and the mercury it soon became complete and the current is then uninterrupted. Resistance, therefore, appears to occasion the development of heat (whatever may be the ultimate cause of the phenomenon), and as this must be inversely as the conducting power when any two of the wires connected continuously are placed in the circuit, that which is the worst conductor must be most heated, and thus platina having the lowest conducting power is ignited before all the rest; and silver which conducts best is not heated red when connected with any of the other metals. Should it be objected that if the electricity meet with greater resistance in one body than in the other, equal quantities cannot be transmitted in equal times by the two substances (a circumstance essential to electrical action), I answer that a body may be propelled through two media of different densities with equal velocity if the propelling forces be proportionate to the resistances; and it is a necessary consequence that whatever effect the passage of the body was capable of producing in the least resisting medium it will produce it in a still greater degree in the most resisting; and if that effect be heat the greater portion will be developed in the latter instance. In the case in question, indeed, there is but one propelling force; but as it is sufficient to overcome the greater resistances the energy is unshaken. That the ignition of the wire is generally first perceptible at the point of contact next the pole of the battery (to whichever pole it be presented), is in favor of the hypothesis. I once thought the phenomenon might be owing to the joint effect of difference of conducting power and inequality of the different metals for heat; but the experiments of Crawford, Leslie, Dalton, Irvine and others, militate against that 3850 idea; for, according to them, the capacities of the iron and platina exceed those of all the other metals, whereas on the supposition alluded to they ought to be inferior. From the foregoing results the order of the conducting powers of the metals tried is silver, zinc, gold, copper, iron and platina. Tin and lead fuse so immediately at the point of contact that they cannot be placed. Between gold and copper the difference is trifling; and with regard to platina and iron their relations to each other in this circumstance seem to be affected by elevations of temperature. It may be observed that the order of the above metals as conductors of electricity nearly follows that of their powers to conduct heat.

In an experiment in which equal lengths of two platina wires of unequal diameter (the larger being one-thirtieth the smaller one-fiftieth of an inch), were placed together in the circuit parallel to each other, the thicker wire was ignited because it conveyed more electricity without proportional increase of cooling surface. When connected continuously the order of ignition was reversed. These two results were foreseen by Dr. Wallaston who suggested the experiments.

The experiments which I now proceed to mention were made with the battery in a high state of excitation; and I consider them as representing nearly the maximum of effect which it is capable of producing. As the quantity of acid was increased from time to time and that previously added often almost spent before fresh was put in, it is not easy to say exactly what proportion it bore to the water; perhaps the largest may be stated to be about one-twentieth. On this as on former occasions, I found a mixture of nitrous and sulphuric acids to produce the most powerful and permanent effects.

Exp. 1. Five feet six inches of platina wire, $\frac{11}{100}$ of an inch in diameter, were heated red throughout visible in full daylight.

Exp. 2. Eight feet six inches of platina wire, $\frac{44}{100}$ of an inch in diameter, were heated red.

3851 Exp. 3. A bar of platina one-sixth of an inch square and two and a quarter inches long was also heated red and fused at the end, and,

Exp. 4. A round bar of the same metal $\frac{276}{1000}$ of an inch in diameter and two and one-quarter inches in length was heated bright red throughout.

Exp. 5. Fine points of boxwood charcoal intensely ignited in chlorine neither suffered any change nor produced any in the gas. The result was similar when heated in azote.

I next tried the power of the battery to fuse several refractory substances. The subject of experiment was placed in a small cavity made in a piece of well-burnt boxwood charcoal floating on the surface of the mercury in one of the basins above mentioned and the circuit completed by another piece of charcoal communicating by stout copper wire with the other basin.

Exp. 1. Oxide of tungsten, which (as well as all the other metallic oxides operated on) had been previously intensely ignited in a charcoal crucible in a powerful furnace fused and was partially reduced. The metal grayish white, heavy, brilliant and very brittle.

Exp. 2. Oxide of tantalum. A very small portion fused. The grains have a reddish-yellow color and are extremely brittle.

Exp. 3. Oxide of uranium; fused but not reduced.

Exp. 4. Oxide of titanium; fused, not reduced, when intensely heated it burned, throwing off brilliant sparks like iron.

Exp. 5. Oxide of cerium; fused, and when intensely heated it burnt with a large vivid white flame, and was partly volatilized, but not reduced. The fused oxide on exposure for a few hours in the air fell into a light-brown powder containing numerous shining particles of a silvery lustre interspersed amongst it, and exhaled an odor similar to that of phosphuretted hydrogen.

Exp. 6. Oxyde of molybuena; readily fused and reduced. The metal is very brittle, of a steel-gray color, and soon becomes coated with a thin coat of purple oxide.

3852 Exp. 7. Compound ore of iridium and osmium; fused into a globule.

Exp. 8. Pure iridium; fused into an imperfect globule not quite free from small cavities and weighing 7.1 grains. The metal is white, very brilliant, and in its present state its specific gravity is 18.68 which must be much too low on account of porous state of the globule. In the minutes of the experiments in July, 1813, mention is made of the fusion of a small portion of pure iridium into a globule weighing $\frac{62}{100}$ of a grain which had been previously submitted to the action of a battery of 2,000 plates of four inches square without melting.

Exp. 9. Ruby and sapphire were not fused.

Exp. 10. Blue spinel ran unto a slag.

Exp. 11. Gadolinite fused into a globule.

Exp. 12. Magnesia was agglutinated.

Exp. 13. Zircon from Norway was imperfectly fused.

Exp. 14. Quartz, silex, and plumbago were not affected.

In the year 1796, M. Clouet, converted iron into steel by cementation with the diamond with the view of confirming the nature of that substance and of ascertaining the exact state in which the carbon exists in steel. Clouet had also previously formed steel by cementation with carbonate of lime. Mr. Mushet repeated this experiment, using instead of the carbonate caustic lime, and obtained also what he considered to be cast steel; whence he concluded that the carbon necessary to convert the iron into steel had not been fur-

nished as Clouet supposed by decomposition of the carbonic acid, but that it had found its way from the ignited gases of the furnace to the iron. This result occasioned suspicions of the accuracy of the deductions from the experiment with the diamond; and Mr. Moshet accordingly at the suggestion of the editor of the Philosophical Magazine repeated the experiment made at the Polytechnic School only keeping out the diamond. The results (for he made several experiments) uniformly gave him good cast steel, whence he concludes that we are still without any satisfactory or conclusive proof of the steelification of iron solely by means of the dia-
3853 mond; and adds that he doubts whether the diamond afforded even one particle of carbon to the iron. The details of both Clouet's and Mushet's experiments may be found in the fifth volume of the Philosophical Magazine. Sir George M'Kenzie repeated both Clouet's experiments, and those of Mr. Mushet and obtained results confirming the conclusions of the French chemists. The labors of this gentleman, indeed, seems sufficiently conclusive; but if a doubt should remain, it occurred to Mr. Pepys that the battery would afford an *experimentum crucis* on the subject; and his ingenuity readily suggested a mode of making it every way unobjectionable. He bent a wire of pure soft iron so as to form an angle in the middle in which part he divided it longitudinally by a fine saw. In the opening so formed he placed diamond powder securing it in its situation by two finer wires laid above and below it and kept from shifting by another small wire bound firmly and closely around them. All the wires were of pure soft iron and the part containing the diamond powder was enveloped by thin leaves of talc. Thus arranged the apparatus was placed in the electrical circuit when it soon became red hot and was kept so for six minutes. The ignition was so far from intense that few who witnessed the experiment expected, I believe, any decisive result. On opening the wire, however, Mr. Pepys found that the whole of the diamond had disappeared; the interior surface of the iron had fused into numerous cavities notwithstanding the very moderate heat to which it had been exposed; and all that part which had been in contact with the diamond was converted into perfect blistered steel. A portion of it being heated red and plunged into water became so hard as to resist the file and to scratch glass. This result is conclusive, for as the contact of any carbonaceous substance except the included diamond was effectually guarded against, to that alone can the change produced in the iron be referred. This experiment will also probably be deemed fatal to the opinion of those mineraleogists (if they do still maintain that opinion), who class the diamond with substances of siliceous genus.

3854 When dry caustic potash was exposed to the intense heat between the two pieces of charcoal, it fused and appeared to decompose, throwing off a large volume of the peculiar purple-red color that attends the combustion of potassium. When moist caustic potash was placed in the circuit the water only was decomposed.

I endeavored to ascertain if there be any difference in the degree of heat produced at either pole of the battery by placing two small earthenware cups, each containing an equal weight of mercury in the circuit and connected together by a platina wire of such size and length as to be kept constantly ignited. The mercury in the cup connected with the zinc end of the battery attained in twenty minutes the temperature of 120°; that in the other cup, 112°.

The battery, even in its most active state, communicated no charge to the Leyden foil.

I give the following experiment, the last with which I shall occupy the time of the society without comment.

I separated all the zinc from the copper plates by dividing the leaden straps that united them; and then by means of other leaden straps I connected all the zinc plates together as one plate, and all the copper plates in the same manner; thus reducing the whole battery to only two plates, each presenting a surface of 1,344 square feet, reckoning the copper surface as only equal to the zinc. When the plates thus arranged were suspended quite out of contact with the acid a communication was made between the two metallic surfaces by means of a platina wire $\frac{1}{5000}$ of an inch diameter and about $\frac{1}{30}$ of an inch long with every possible attention to ensure a perfect contact; but, although the experiment was made in the dark, not the slightest appearance of ignition was perceptible in the minute wire by which these extensive surfaces were connected. It is known, I believe, to almost every member of this society that Dr. Wollaston has shown with the delicate apparatus invented by him that the platina wire of the same dimensions as that just mentioned is instantly ignited by a single pair of plates one inch square on
3855 being immersed in a diluted acid. The ratio of the areas of
the plates of the respective batteries is 1 to 48,384. When the plates of the larger battery in the usual order of arrangement were immersed in mere pump water previous to any acid having been put into the cells, they ignited one-fourth of an inch of platina wire, $\frac{1}{200}$ of an inch diameter, and fused the end of it into a perfect globule.

Philosophical Transactions of the Royal Society of London.

Volume 20, published in London in 1820, under section 2, page 21—title, Comparative Experiments on the Illuminating and Heating Powers of Olefiant Coal and Oil Gases and on some General Properties of Radiant Matter, at pages 26 and 27.

10. There are certain substances, the chemical relations of which are singularly affected by the influence of direct solar rays. Among these the mixture of chlorine and hydrogen is most remarkable: If kept in common daylight but out of direct sunshine, the gases do not act upon each other; but the moment the mixture is placed in the sunshine the muriatic acid begins to be formed. I therefore hoped that this property might be applicable in certain photomet-

rical experiments. I exposed a mixture of equal volumes of chlorine and hydrogen in a tube inverted over water capable of holding about four cubical inches and blown into a thin bulb at its upper extremity to the brilliant effects produced by a large olefiant gas flame; it was exposed for 15′, but underwent no other change than a slight increase of bulk, acting as an air thermometer.

11. It now occurred to me to try how far any effect would be produced by the more intense light of the voltaic battery, and I placed the tube containing the mixed gases in a darkened room within about an inch of the charcoal points connected with an apparatus of 100 pairs of plates highly charged; upon making the contact the effect of the light upon the mixed gases was very remarkable; fumes of muriatic vapor were instantly produced, the water rose in the tube in consequence of the production of muriatic acid, and in about five minutes the absorption was entire; but the most curious circumstances was that in two instances an explosion of the gases took place the moment they felt the impulse of the electric light.

XXIX.—Farther researches on the magnetic phenomena produced by electricity; with some new experiments on the properties of electrified bodies in their relations to conducting powers and temperature, by Sir Humphrey Davy, bart., F. R. S.

Read July 5, 1821.

I. In my letter to Dr. Wollaston on the new facts discovered by M. Oersted, which the society has done me the honor to publish, I mentioned that I was not able to render a bar of steel magnetic by transmitting the electrical discharge across it through a tube filled with sulphuric acid; and I have likewise mentioned that the electrical discharge passed across a piece of steel through air rendered it less magnetic than when passed through a metallic wire; and I attributed the first circumstance to the sulphuric acid being too bad a conductor to transmit a sufficient quantity of electricity for the effect; and the second to the electricity passing through the air in a more diffused state than other metals.

To gain some distinct knowledge on the relations of the different conductors to the magnetism produced by electricity, I instituted a series of experiments which led to very decisive results, and confirmed my first views.

II. I found that the magnetic phenomena were precisely the same whether the electricity was small in quantity and passing through good conductors of considerable magnitude; or whether

the conductors were so imperfect as to convey only a small quantity of electricity; and in both cases they were neither attractive of
each other nor of iron filings, and not affected by the mag-
3858 net; and the only proof of their being magnetic was their
occasioning a certain small deviation of the magnetized needle.

Thus, a large piece of charcoal placed in the circuit of a very powerful battery being a very bad conductor compared with the metals, would not affect the compass needle at all unless it had a very large contact with the metallic part of the circuit; and if a small wire was made to touch it in the circuit, only in a few points that wire did not gain the power of attracting iron filings; though when it was made to touch a surface of platinum foil coiled around the end of the charcoal a slight effect of this kind was produced. And in a similar manner fused hydrate of potassa, one of the best of the imperfect conductors, could never be made to exert any attractive force on iron filings; nor could the smallest filaments of cotton moistened by a solution of hydrate of potassa placed in the circuit be made to move by the magnet; nor did steel needles floating on cork on an electrized solution of this kind placed in the voltaic circuit gain any polarity; and the only proof of the magnetic powers of electricity passing through such a fluid was afforded by its effect upon the magnetized needle when the metallic surfaces plunged in the fluid were of considerable extent. That the mobility of the parts of fluids did not interfere with their magnetic powers as developed by electricity, I prove by electrifying mercury and Newton's metal fused in small tubes. These tubes, placed in a proper voltaic circuit, attracted iron filings and gave magnetic power to needles; nor did any agitation of the mercury or metal within either in consequence of mechanical motion or heat, alter or suspend their polarity.

III. Imperfect conducting fluids do not give polarity to steel when electricity is passed through them; but electricity passed through air produces this effect. Reasoning on this phenomenon and on the extreme mobility of the particles of air, I concluded, as M. Arrago had likewise done, from other considerations that the voltaic current in air would be affected by the magnet. I failed in my first
trial, which I have referred to in a note to my former paper,
3859 and in other trials made since, by using too weak a magnet;
but I have lately had complete success; and the experiment exhibits a very striking phenomenon.

Mr. Pepys having had the goodness to charge the great battery of the London institution, consisting of 2,000 double plates of zinc and copper, with a mixture of 1,168 parts of water, 108 parts of nitrous acid and 25 parts of sulphuric acid, the poles were connected by charcoal so as to make an arc or column of electrical light varying in length from one to four inches, according to the state of rarefication of the atmosphere in which it was produced; and a powerful magnet being presented to this arc or column having its pole at a very acute angle to it, the arc or column was attracted or repelled with a rotary motion, or made to revolve by placing the poles in different positions according to the same law as the electrified cylinders of platinum described in my last paper, being repelled when the negative pole was on the right hand by the north pole of the magnet, and attracted by the south pole and *vice versa*.

It was proved by several experiments that the motion depended entirely upon the magnetism and not upon the electrical inductive power of the magnet, for masses of soft iron or of other metals produced no effect.

The electrical arc or column of flame was more easily affected by the magnet, and its motion was more rapid when it passed through dense than through rarefied air; and in this case the conducting medium or chain of aeriform particles was much shorter.

I tried to gain similar results with currents of common electricity sent through flame and *in vacuo*. They were always affected by the magnet; but it was not possible to obtain so decided a result as with voltaic electricity, because the magnet itself became electrical by induction and that whether it was insulated or connected with the ground.

(FOOT-NOTE.—I made several experiments on the effects of currents of electricity simultaneously passing through air in different states of rarefication in the same and different directions, both from
the voltaic and common electrometers; but I could not es-
3860 tablish the fact of their magnetic attractions or repulsions
with regard to each other, which probably was owing to the impossibility of bringing them sufficiently near.)

IV. Metals, it is well known, readily transmit large quantities of electricity, and the obvious limit to the quantity which they are capable of transmitting seems to be their fusibility or volatilization by the heat which electricity produces in its passage through bodies.

Now, I had found in several experiments that the intensity of this heat was connected with the nature of the medium by which the body was surrounded; thus, a wire of platinum which was readily fused by transmitting the charge from a voltaic battery in the exhausted receiver of an air pump, acquired in air a much lower degree of temperature. Reasoning on this circumstance, it occurred to me that by placing wires in a medium much denser than air, such as ether, alcohol, oils or water, I might enable them to transmit a much higher charge of electricity than they could convey without being destroyed in air, and thus not only gain some new results as to the magnetic state of such wires, but likewise perhaps determine the actual limits to the powers of different bodies to conduct electricity and the relations of these powers.

A wire of platinum of three inches in length was fused in air by being made to transmit the electricity of two batteries of ten zinc plates of four inches, with double copper strongly charged; a similar wire was placed in sulphuric ether and the charge transmitted through it. It became surrounded by globules of gas, but no other change took place, and in this situation it bore the discharge from twelve batteries of the same kind exhibiting the same phenomena. When only about an inch of it was treated by this high power in ether it made the ether boil and became white hot under the globules of vapor, and then rapidly decomposed the ether, but it did not fuse. When oil or water was substituted for the ether, the length of the wire remaining the same, it was partially covered with small globules of gas, but did not become red hot.

3861 Though, on trying the magnetic powers of this wire in water, they were found to be very great, and the quantity of iron filings that it attracted was such as to form a cylinder round it of nearly the tenth of an inch in diameter.

To ascertain whether short lengths of fine wire, prevented from fusing by being kept cool, transmitted the whole electricity of powerful voltaic batteries, I made a second independent circuit from the ends of the battery with silver wires in water, so that the electrical decomposition of the water indicated a residuum of electricity in the battery. Operating in this way, I found that an inch of wire of platinum of one two hundred and twentieth, kept cool by water, left a great residual charge of electricity in a combination of twelve batteries of the same kind as those above mentioned, and after making several trials I found that it was barely adequate to discharge six batteries.

V. Having determined that there was a limit to the quantity of electricity which wires were capable of transmitting, it became easy to institute experiments on the different conducting powers of different metallic substances, and on the relation of this power to the temperature, mass, surface or length of the conducting power and to the conditions of electro-magnetic action.

These experiments were made as nearly as possible under the same circumstances, the same connecting copper wires being used in all cases, their diameter being more than $\frac{1}{10}$ of an inch and the contact being always preserved perfect; and parts of the same solutions of acid and water were employed in the different batteries and the same silver wires and broken circuit with water were employed in the different trials, and when no globules of gas were observed upon the negative silver wire of the second circuit it was concluded that the metallic conducting chain or the primary circuit was adequate to the discharge of the combination. To describe more minutely all the precautions observed would be tedious to those persons who are accustomed to experiments with the voltaic apparatus, and unintelligible to others; and after all, in researches of
this nature it is impossible to gain more than approxima-
3862 tions to true results, for the gases disengaged upon the plates
the different distances of the connecting plates and the slight difference of time in making the connections all interfere with their perfect accuracy.

The most remarkable general result that I obtained by these researches and which I shall mention first, as it influences all the others, was that the conducting power of metallic bodies varied with the temperature and was lower in some inverse ratio as the temperature was higher.

Thus a wire platinum of $\frac{1}{220}$ and 3 inches in length when kept cool by oil discharged the electricity of two batteries or of twenty double plates; but when suffered to be heated by exposure in the air, it barely discharged one battery.

Whether the heat was occasioned by the electricity or applied to it from some other source, the effect was the same. Thus, a wire of platinum of such length and diameter as to discharge a combination without being considerably heated, when the flame of a spirit lamp was applied to is so as to make a part of it red hot, lost its power of dischargiug the whole electricity of the battery as was shown by the disengagement of abundance of gas in the secondary circuit, which disengagement ceased as soon as the source of heat was withdrawn.

There are several modes of exhibiting this fact so as to produce effects which, until they are witnessed, must almost appear impossible. Thus, let a fine wire of platinum of four or five inches in length be placed in a voltaic circuit so that the electricity passing through it may heat the whole of it to redness and let the flame of a spirit lamp be applied to it so as to heat that part to whiteness, the rest of the wire will instantly become cooled below the point of visible ignition. For the converse of the experiment let a piece of ice or stream of cold air be applied to a part of the wire, the other parts will immediately become much hotter, and from a red will rise to a white heat. The quantity of electricity that can pass through that part of the wire submitted to the changes of temperature is so much smaller when it is hot than when it is 3863 cold that the absolute temperature of the whole wire is diminished by heating a part of it, and *vice versa* increased by cooling a part of it.

In comparing the conducting powers of different metals, I found much greater difference than I had expected. Thus, six inches of silver wire of one two hundred and twentieth discharged the whole of the electricity of 65 pairs of plates of zinc and double copper made active by a mixture of about one part of nitric acid of commerce, and 15 parts of water. Six inches of copper wire of the same diameter discharged the electricity of 56 pairs of the same combination, six inches of tin of the same diameter carried off that of 12 only, the same quantity of wire of platinum that of 11, and of iron that of 9. Six inches of wire of lead of $\frac{1}{200}$ seemed equal in their conducting powers to the same length of copper wire of $\frac{1}{220}$. All the wires were kept as cool as possible by immersion in a basin of water.

(FOOT NOTE.—Water is so bad a conductor that in experiments of this kind its effect may be neglected altogether; and these effects were equal in all the experiments.)

I made a number of experiments of the same kind, but the results were never precisely alike, though they sometimes approached very near to each other. When the batteries were highly charged so that the intensity of the electricity was higher, the differences were less between the best and worst conductors, and they were greater when the charge was extremely feeble. Thus, with a fresh charge of about one part of nitric acid, and nine parts of water wires of $\frac{1}{220}$ of silver and platinum of 5 inches long discharged respectively, the electricity of thirty and seven double plates.

Finding that when different portions of the same wire plunged in a non-conducting fluid were connected with different parts of the same battery equally charged, their conducting powers appeared in the inverse ratio of their lengths; so when 6 inches of wire of platinum of $\frac{1}{220}$ discharged the electricity of ten double plates, 3
3864 inches discharged that of 20, $1\frac{1}{2}$ inch, that of forty, and 1
inch that of sixty; it occurred to me that the conducting powers of the different metals might be more easily compared in this way, as it would be possible to make the contacts in less time than when the batteries were charged, and, consequently, with less variation in the charge.

Operating in this way, I ascertained that in discharging the electricity of 60 pairs of plates, 1 inch of platinum was equal to about 6 inches of silver, to $5\frac{1}{2}$ inches of copper, to four of gold, to 3.8 of lead, to about $\frac{9}{10}$ of palladium, and $\frac{8}{10}$ of iron, all the metals being in a cooling fluid medium.

I found, as might have been expected, that the conducting power of a wire for electricity in batteries of the size and number of plates just described, was nearly directly as the mass; thus, when a certain length of wire or platinum discharged one battery, the same length of wire of six times the weight discharged 6 batteries; and the effect was exactly the same, provided the wires were kept cool, whether the mass was a single wire or composed of six of the smaller wires in contact with each other. This result alone showed that surface had no relation to conducting power, at least for electricity of this kind, and it was more distinctly proved by a direct experiment; equal lengths and equal weights of wire of platinum, one round and one flattened by being passed transversely through rollers so as to have six or seven times the surface, were compared as to conducting powers. The flattened wire was the best conductor in air, from its greater cooling powers, but in water no difference could be perceived between them.

VI. I tried to make a comparison between the conducting powers of fluid menstrua and charcoal and those of metals. Six inches of platinum foil $1\frac{1}{5}$ inches broad were placed in a vessel which could be filled with any saline solution, and a similar piece of platinum
placed opposite at an inch distant; the whole was then made
3865 part of a voltaic circuit, which had likewise another termina-
tion by silver wires in water, and a solution of salts added till gas ceased to be liberated from the negative silver wire. In several trials of this kind it was found that the whole of the surface of six inches, even with the strongest solutions of common salt, was insufficieut to carry off the electricity even of two pairs of plates only, whereas an inch of wire of platinum of $\frac{1}{220}$ (as has been stated) carried off all the electricity of sixty pairs of plates. The gas liberated upon the surface of metals when they are placed in

---

(Foot Note.—A foot of this wire weighed 1.13 grains. A foot of the other 6.7 grains).

fluid renders it impossible to gain accurate results, but the conducting power of the best fluid conductors, it seems probable from this experiment, must be some hundreds of thousand times less than those of the worst metallic conductors.

A piece of well-burnt compact boxwood charcoal was placed in the circuit, being $\frac{3}{10}$ of an inch wide by $\frac{1}{10}$ thick, and connected with large surfaces of platinum. It was found that 1 inch and $\frac{2}{10}$ carried off the same quantity of electricity as 6 inches of wire of platinum of $\frac{1}{220}$.

VII. I made some experiments with the hope of ascertaining the exact change of ratio of the conducting powers dependent upon the change of the intensity and quantity of electricity, but I did not succeed in gaining any other than the general result, that the higher the intensity of the electricity the less difficulty it had in passing through bad conductors, and several remarkable phenomena depend upon this circumstance.

Thus in a battery where the quantity of the electricity is very great and the intensity very low, such as one composed of plates of zinc, zinc and copper are arranged as to act only as single plates of from 20 to 30 feet of surface each and charged by a weak mixture of acid and water. Charcoal made to touch only in a few points is almost as much an insulating body as water and cannot be ignited, nor can wires of platinum be heated when their diameter is less than $\frac{1}{80}$ of an inch and their length 3 or 4 feet, and a foot of platinum wire of $\frac{1}{30}$ is scarcely heated by such a battery, whilst the
same length of silver wire of the same diameter is made red
3866 hot, and the same lengths of thicker wires of platinum or
iron are intensely heated.

The heat produced where electricity of considerable intensity is passed through conductors must always interfere with the exact knowledge of the changes of their conducting powers, as is proved by the following experiment. A battery of twenty pair- of plates of zinc and copper plates ten inches by six was very highly charged with a mixture of nitric acid and water, so as to exhibit a considerable intensity of electrical action, and the relative conducting powers of silver and platinum in air and water ascertained by means of it. In air six inches of wire of platinum of $\frac{1}{80}$ discharged only four double plates, whilst six inches of silver wire of the same diameter discharged the whole combination; the platinum was strongly ignited in this experiment, whilst the silver was scarcely warm to the touch. On cooling the platinum wire by placing it in water, it was found to discharge ten double plates. When the intensity of the electricity is very high, however, even the cooling powers of fluid media are of little avail; thus, I find that fine wire of platinum was fused by the discharge of a common electrical battery under water; so that the conducting power must always be diminished by the heat generated in a greater proportion as the intensity of the electricity is higher.

It might at first be supposed that when a conductor placed in the circuit left a residu-m of electricity in any battery increase of the power of the battery or of its surface could not enable it to carry through any additional quantity. This, however, is far from being the case.

When saline solutions were placed in the circuit of a battery of twenty plates, though they discharged a very small quantity only of the electricity when the troughs were only one-quarter full, yet their chemical decomposition exhibited the fact of a much larger quantity passing through them when the cells were filled with fluid.

And a similar circumstance occurred with respect to a wire
3867 of platinum, of such a length as to leave a considerable residuum
in a battery when only half its surface was used; yet, when the whole surface was employed it became much hotter and nevertheless left a still more considerable residuum.

VIII. I found long ago that in increasing the number of alternations of similar plates, the quantity of electricity seemed to increase as the number, at least as far as it could be judged of by the effects of heat upon wires; but only within certain limits, beyond which the number appeared to diminish rather than increase in quantity. Thus, the 2,000 double plates of the London institution when arranged as one battery would not ignite so much wire as a single battery of ten plates with double copper.

It is not easy to explain this result. Does the intensity mark the rapidity of the motion of the electricity, or merely its diminished attraction become less in proportion as the circuit through which it passes or in which it is generated contains a greater number of alternations of bad conductors?

Mr. Children in his account of the experiments made with his battery of large plates has ingeniously referred the heat produced by the passage of electricity through conductors to the resistance it meets with and has supposed what proves to be the fact that the heat is in some inverse ratio to the conducting power. The greatest heat, however, is produced in air, where there is reason to suppose the least resistance; and as the presence of heat renders bodies worse conductors another view may be taken—namely, that the excitation of heat occasions the imperfection of the conducting power. But till the causes of heat and of electricity are known, and of that peculiar constitution of matter which excites the one and transmits or propagates the other, our reasoning on this subject must be inconclusive.

I found that when equal portions of wires of the same diameter, but of different metals, were connected together in the circuit of a powerful voltaic battery acting as two surfaces, the metals were heated
in the following order: Iron most, then palladium, then plat-
3868 ina, then tin, then zinc, then gold, then lead, then copper,
and silver least of all. And from one experiment in which similar wires of platinum and silver joined in the same circuit were placed in equal portions of oil, it appeared that the generation of heat was nearly inversely as their conducting power. Thus the silver raised the temperature of the oil only 4°, whilst the platinum raised it 22°. The same relations to heat seem to exist whatever is the intensity of the electricity; thus, circuits of wire placed under

water and acted on by the common electrical discharge were heated in the same order as by the voltaic battery, as was shown by their relative fusion; thus iron fusing before platinum, platinum before gold and so on.

If a chain be made of wire of platinum and silver, in alternate links soldered together the silver wire being four or five times the diameter of the platinum, and placed in a powerful voltaic circuit, the silver links are not sensibly heated, whilst those of the platinum become intensely and equally ignited. This is an important experiment for investigating the nature of heat. If heat be supposed a substance, it cannot be imagined to be expelled from the platinum, because an unlimited quantity may be generated from the same platinum, *i. e.*, as long as the electricity is excited or as often as it is renewed. Or if it be supposed to be identical with or an element of electricity, it ought to bear some relation to its quantity, and might be expected to be the same in every part of the chain or greatest in those parts nearest the battery.

IX. The magnetism produced by electricity. though with the same conductors, it increases with the heat, as I mentioned in my last paper, yet with different conductors I find it follows a very different law. Thus, when a chain is made of different conducting wires and they are placed in the same circuit, they all exhibit equal magnetic powers and take up equal quantities of iron filings, so that the magnetism seems directly as the quantity of electricity which they transmit. And when in a highly powerful voltaic battery, wires of the same diameters and lengths, and of 3869 which the best conducting is incapable of wholly discharging the battery, are made separately and successively to form the circuit, they take up different quantities of iron filings in some direct proportion to their conducting powers.

Thus, in one experiment two inches of wire of $\frac{1}{30}$ of an inch being used, silver took up 32 grains, copper 24, platinum 11, and iron 8.2.

3870 DEFENDANT'S EXHIBIT PHILOSOPHICAL TRANSACTIONS, PAPER No. 5. W. T. F., Spec. Ex'r.

Philosophical Transactions of the Royal Society of London for the Year 1839.

Part I, vol. 39, page 89. Fifth letter on voltaic combinations, with some account of the effects of a large constant battery. Addressed to Michael Faraday, Esq., D. C. L., F. R. S., Fullerian prof. chem., Royal institution, &c., &c., &c. By J. Frederick Daniell, Esq., F. R. S., prof. chem. in Kings college, London. Received April 11. Read May 30, 1839.

MY DEAR FARADAY: In my last letter to you which the Royal society have done me the honor to publish in the Philosophical Transactions for 1838, I observed that the "principal circumstance which might be supposed to limit the power of an active combination within a conducting sphere in any given electrolyte is the resistance of that electrolyte which increases in a certain ratio to its depth or thickness." The superficial measure of the conducting sphere and the distance of the generating metal or the depth and resistance of the electrolyte are in fact vari-ble conditions in a voltaic combination upon which its efficiency depends; and their relations require further investigation before we shall be able to determine what may be the proper proportions for the economical application of the power to useful purposes. I shall venture, therefore, to trouble you with results of some further experiments upon the subject and upon different combinations of the constant battery before I proceed to communicate some observations upon electrolysis which I trust you will find not without interest and to which according to my plan my attention has been lately exclusively directed.

3871 Looking for a moment upon the affinity which circulates in the battery as a radiant force, it seemed desirable to ascertain what would be the result of intercepting the rays by the conducting surface nearer to their centre than in the arrangements which have been previously described as the relation of the generating and conducting metals to each other might be thereby more clearly ascertained.

For this purpose, I constructed a battery of ten cylinders of copper 19 inches in length by 1½ inches in diameter. As the quantity of acid and sulphate of copper which the cylinders could contain was too small it was necessary to provide for the perpetual renovation of the charge as the zinc became dissolved and the copper precipitated. This was effected by connecting all the membranes which held the acid and the zinc rods at their lower end with a pipe terminating in a stop-cock. Their upper ends were fixed in a cistern from which they could be gradually supplied with fresh acid as the saturated acid flowed out below. All the exterior cells formed between the membrances and the copper cylinders also terminated below in a common reservoir surrounding the former pipe by which their exhausted contents could be drawn off as a fresh supply of sulphate of copper was furnished from above by an exterior cistern holding the solution. When the battery was in action a saturated solution of sulphate of copper thus supplied from the top could be drawn off almost colorless at the bottom; and it remained constant for a considerable time.

The effect produced was 4½ inches of mixed gases per minute measured in the vol*l*ameter formerly described.

I compared this result with that obtained from a battery of ten cylinders 20 inches in length and 3½ inches in diameter which gave in the same vol*l*ameter 11 cubic inches per minute. The surfaces of the conducting cylinders were respectively 89.5 square inches and 220 square inches; and the products of gases in equal times were nearly in the same proportion as the surfaces. The zinc rods were 1½ inches in diameter in both cases.

3872 I next proceeded to compare two small hemispheres of copper with the large hemisphere of brass of 9½ inches in diameter, formerly described. They were fitted up as before as single circuits with a zinc ball of 1 inch diameter first placed in the membranes below the surface of the solution of copper. The measure made use of was the calorific galvanometer; the first was 4 inches diameter and produced a permanent effect of 45° upon the thermometer. The second of 2½ inches diameter produced an effect of 29°. The effect of the large hemisphere was 90°. Here it will be observed that the action was by no means proportioned to the surfaces of the conducting hemispheres, but approximated more nearly to the simple ratios of their diameters.

Hence, it would appear that the circulating force of both a simple and compound voltaic circuit increased with the surface of the conducting plate surrounding an actual centre; but the experiments are not sufficient to determine the law of the increase.

I now constructed a battery of ten larger cylinders of four inches diameter, the arrangement in everything being the same as before; I found that the action was reduced to one-half the amount of mixed gases in the vol*t*ameter per minute being only 5½ cubic inches. The experiments were repeated several times, and the action maintained for several hours and always with consistent results. This extraordinary and sudden decline of force requires further investigation; and indeed the only conclusion which we can at present draw from the experiments which I have just detailed, but which is of considerable practical importance, is that cylinders of 3½ inches diameter form much more effective producing plates in a voltaic arrangement than cylinders of either greater or less diameter. It must, however, be borne in mind that this has only been proved by a series of ten cells; for it is highly probable that the limits of efficiency may change with the number of the series.

The following experiments with the different combinations which may be made with twenty cylinders throw some light on the 3873 question of the influence of the numbers of a series, the diameter of the numbers of which is limited to 3½ inches. The cylinders were 20 inches in height and the zinc rods were ⅝ of an inch in diameter. The electrolyte consisted of eight parts of water and one part of oil of vitriol by measure, and in the exterior divisions of the cells was a saturated sulphate of copper. The temperature was about 65°; the duration of each experiment was one minute.

First Set of Experiments.

No. of cells	1	2	3	4	5	10	15	20
Cubic inches of gas	0	Just visible.	1⅛	3⅞	6	12¼	15⅓	17¼

Second Set of Experiments.

	All cells direct.	1 inverted.	2 invert.	3 invert.
Cubic inches of gas	17½	15½	12¾	10½

	4 invert.	5 invert.	6 invert.	7 invert.	8 invert.
Cubic inches of gas	8½	5½	3½	15⅛	1⅛

	9 invert.
Cubic inches of gas	Just visible.

Third Set of Experiments.

Number of double cells	5	10
Cubic inches of gas	11	20

Fourth Set of Experiments.

	5 triple cells.	5 quadruple cells.
Cubic inches of gas	14½	15⅔

When a series of 5 single cells was connected with a series of 5 double cells and the same voltameter employed the amount of gas was 15⅔ cubic inches. Each double series alone gave 11 cubic inches.

From these experiments it appears that the most advantageous adjustment of active force and resistance is in the series of ten single cells when they are of the diameter of 3½ inches, and that the largest amount of work which can be derived from twenty such cells is when they are arranged in two series of ten; for

3874

Cells.	Cubic in.	Cells.	Cubic in.	Cells.	Cubic in.
10 give	12½	5 give	6	4 give	3⅞
	2		4		5
20	25	20	24	20	19⅜

20 in single series give 17½ cubic inches. 10 double cells give 20 cubic inches.

Cells.	Cubic in.	Cells.	Cubic in.
5 double give	11	5 quadruple give	15⅔
	2		
20	22	20	15⅔

I now combined in a single series a battery of 70 cells of the same dimensions and charged in the same manner for the purpose of observing chiefly the effects of light and heat produced by the current, in a state of high intensity and constant action. The interior cells were formed of light porous earthenware and answered their purpose perfectly, offering no more obstruction to the current than the membranes and being much more convenient in use.

The quantity of decomposition per minute from a voltameter with the usual charge of dilute acid was only 17 cubic inches; while with distilled water the passage of a current was scarcely indicated by a few bubbles of gas which arose from the electrodes.

The flame between charcoal points was of considerable volume and formed a continuous arch when the points were separated to about three-quarters of an inch. This striking distance did not appear to be increased in the flask exhausted by the air pump. The light and radiant heat were most intense and proved highly injurious — the eyes of many of the party who did me the honor of assisting me in my experiments. In my own case, although protected by dark gray glasses of double thickness, a high state of inflammation was produced, which it required very active medical treatment to subdue; and as you well know in others even the application of leeches was found to be necessary. The whole of my face was also scorched and inflamed as if it had been exposed for

many hours to a bright midsummer sun. When reflected
3875 from an imperfect parabolic metallic mirror in a lantern the
rays were collected into a focus by a glass lens and readily
burnt a hole in paper at many feet from their source. The heat was quite intolerable to the hand when held near the lantern.

Paper steeped in nitrate of silver and afterwards dried was speedily burnt brown in the light; and when a piece of fine wire gauze was held before it the pattern of the latter appeared in white lines corresponding to the parts which it protected.

The phenomenon of the transfer of the charcoal from one electrode to the other, which I believe was first remarked by Dr. Hare, was abundantly produced. The transfer took place from the zincode (or positive pole, or charcoal connected with the last copper cylinder of the battery) to the platinode (the negative pole, or charcoal connected with the last zinc rod of the battery).

(FOOT-NOTE.—I have so strongly felt the want of some distinctive names for the two poles of the battery consistent with the principles of nomenclature which you have adopted, that I have ventured to propose those mentioned above and have constantly used them in my lectures. The anode and cathode have relations to the surfaces of the electrolyte, and if we distinguish the electrodes themselves as the anelectrode and the cathelectrode confusion is apt to arise; I find practically that students easily recollect that the zincode is that electrode which in the regular battery would be constructed of zinc and the platinode of platinum.)

And in the former a sharp well-defined cup-like cavity was produced and on the latter a corresponding protuberance or nipple. The carbon of the latter proved to be very hard and had the rough mammillated structure of the carbon which is found coating the interior of gas retorts. When a platinum rod was substituted for the charcoal at the platinode the transfer of the charcoal from the zincode still took place, and the metal became coated with carbon
which was beautifully molded at its extremity. When this
3876 arrangement was reversed and the zincode was formed of
platinum, and the platinode of charcoal, particles of platinum were transferred and the charcoal became covered with distinct and numerous globules of the fused metal.

The transfer of matter of such dissimilar kinds in this definite direction renders it probable that it is essential to the disruptive discharge and is entirely analogous to the transfer of matter which has been observed by Fusineri in all cases of the Leyden discharge, and of the discharge of atmospheric electricity by lightning.

As connected with this subject, I may recall to your recollection the attempts which were made to produce a spark before contact and in which we reduced the resistance between two platinum wires connecting the two ends of the battery to the utmost possible degree with success. Even when the wires were heated in the flame of a blow-pipe no passage was established. At the suggestion of Sir John Herschel, I adjusted two brass poles connected with the two ends of the battery within a very minute distance of each other, and while in this situation I passed a spark of a small Leyden jar between them and immediately the battery current was established and the brass poles which were hollow were burnt. Is it not probable that the Leyden discharge in this case transferred the conducting matter which was essential to the existence of the voltaic flame, and which was afterwards supplied by its own energy?

The arch of flame between the electrodes was found to be attracted or repelled by the poles of a magnet according as one or other pole was held above or below it, as was first ascertained by Sir H. Davy; and the repulsion was at times so great as to extinguish the flame. When according to the suggestion of Mr. Gassiot the flame was drawn from the pole of the magnet itself included in the circuit it rotated in a very beautiful manner.

(FOOT-NOTE.—This modification of Sir H. Davy's experiment was first made, as I am informed, by Mr. Sturgeon.)

3877 & 3878 When the zincode was connected with the marked pole and the platinode was held over it, the rotation was from west to east, or in the contrary direction to the motion of the hands of a watch; but when the arrangement was reversed and the zincode was connected with the unmarked pole, the rotation was reversed. The flame was also made to rotate by the induction of the magnetism of the earth upon a poker of iron held in the direction of the dip.

The experiment was again varied by leading the current through a spiral twisted round a horseshoe bar of soft iron, and causing the flame to rotate under the influence of its own magnetic force.

The heating power of the battery was very great and the greater intensity of the heat on the side of the zincode than on that of the platinode extremely remarkable. Mr. Gassiot first pointed out to me that when two stout copper wires of $\frac{1}{5}$ of an inch in diameter were connected with the extremities of the battery, and held across each other so that the flame passed between them, the wire at the zincode became red hot while the other remained comparatively cool. A bar of platinum $\frac{1}{8}$ of an inch square freely melted and dropped in large globules in the former situation, but showed no signs of fusion at the platinode.

When the zincode was formed of hard carbon taken from the gas retorts and a cavity ground in it, the most infusible metals placed in it were melted in considerable quantities.

Pure rhodium immediately ran into a perfect globule and burnt with scintillations and a blue light. The native alloy of ir*r*idium and osmium as well as pure ir*r*idium were also completely melted. These metals were kindly supplied to me for the experiments by Mr. Johnson.

Titanium fused instantly and burnt with scintillations very much resembling those from iron.

The native ore of platinum was completely fused, but the mass when cold proved to be very brittle.

After four hours' constant action the power of the battery was found to be undiminished and the amount of the zinc consumed was very small.

3879 In conclusion, I shall briefly describe the results of some experiments on the evolution of the mixed gases from water in a confined space and under constant high pressures which I made from July to October, 1837, and which I intended to have further extended. My objects were to ascertain first, in what manner conduction would be carried on supposing that the tube in which the electrodes were introduced were quite filled with the electrolyte and there were no space for the accumulation of the gases; secondly, whether decomposition having been effected recombination would take place at any given pressure; and thirdly, whether any reaction on the current force of the battery would arise from the additional mechanical force which it would have to overcome.

The first apparatus which I made use of was a stout glass tube into the lower end of which a platinum wire was inserted to form an electrode. This end was hermetically closed and the upper end drowned and fitted with a platinum valve pressed upon by a lever which could be loaded with weights to any required amount. From this valve a wire projected into the tube to form the other electrode. The tube was accurately filled with the standard dilute acid and placed in the battery circuit with a voltameter by which the rate of work and the quantity of the gases disengaged could be ascertained. The battery made use of consisted of ten large cells with the usual charge. Before pressure was applied the rate of work was always ascertained with the tube and voltameter in their places. I tried many experiments with this arrangement; but it will only be necessary to describe the general results.

The pressure was carried up to 98 lbs. upon a circular area of $\frac{3}{4}$ inch diameter, the apparatus appeared to be quite tight for a long time and bubbles of gas evolved from the two wires when the circuit was complete. The liquid became hazy and bubbles of gas seemed to line the tube. The stream of oxygen from the upper wire was projected downward into the liquid as if with considerable force. The liquid ultimately oozed out between the edge of the tube
3880 and the valve, and the experiment was stopped. When the
pressure on the valve was removed a puff of gas took place and the liquid slowly effervesced for a considerable time but was not projected with any violence. The compression tube felt warm to the hand, but not very hot. The quantity of gas which first escaped seemed to bear but a small proportion to that which was indicated by the voltameter included in the circuit and the rate of decomposition was not at all altered by the accumulation of the elastic force.

To carry the experiment as far as the resistance of the glass could conveniently admit of, I caused a compression tube to be made of $\frac{1}{8}$ inch in thickness of the capacity of $1\frac{3}{10}$ cubic inch. Two platinum plates were sealed into its lower end; one cubic inch of standard acid was poured into it, and it was then hermetically sealed at the top. It was placed securely in the battery circuit with a voltameter and the progress of the experiment was watched from a safe distance.

The evolution of the gas which was measured at short intervals took place with perfect regularity and did not appear to be in the slightest degree affected by the gradual increasing compression. In four and one-half minutes, when 19 cubic inches had been collected, the compression tube burst with a loud explosion and the fragments which were very small were scattered all over the laboratory.

If we were to calculate that 19 cubic inches were compressed into the $\frac{3}{10}$ of a cubic inch space unoccupied by the liquid this would be a compression of 63 into 1, and the pressure would amount to nearly 940 pounds upon the square inch; but if — were to reckon, as was probably the case, that two cubic inches of the gases were kept down by the solvent power of the liquid at this high pressure, then the compression would have amounted to 56 into 1, and the pressure to 840 pounds upon the square inch.

It is probable that the means here pointed out might be applied
with advantage to the compression of some of the gases whose
3881 liquefaction you have already affected; and I purpose when
my avocations will permit to return to the experiments with
this view.

I remain, my dear Faraday, your faithful friend,

J. F. DANIELL.

Kings college, London, April 9, 1839.

3882 DEFENDANT'S EXHIBIT PHILOSOPHICAL TRANSACTIONS, PAPER NO. 6. W. T. F., Spec. Ex'r.

Philosophical Transactions of the Royal Society of London for the Year 1832.

Part I, volume 32, at page 292.

XIII.—Experimental researches in voltaic electricity and electro-magnetism by the Rev. William Ritchie, LL. D., F. R. S., prof. of natural and experimental philosophy in the Royal Institution of Great Britain, and professor of natural philosophy and astronomy in the University of London.

Read January 19, 1832.

PART III.

Application of the Preceding Principles to Further Developments in Voltaic Electricity.

20. There are only three substances which can be regarded as good conductors of voltaic electricity: viz: The metals, charcoal, and acidulated water. The metals when employed as conductors seem to have been the only substances whose deflecting energy on the needle has been carefully examined. It appeared to me worth an experiment to ascertain if charcoal deflected the needle and that

too with the same energy as metal conducting an equal quantity of voltaic electricity. This was ascertained with the following arrangement. Exp. VIII. A piece of charcoal about 1½ inches long was placed between two slips of copper fixed perpendicularly in a piece of wood and an astatic needle suspended by a fibre of silk brought over the middle of the charcoal.

Fig. 6 will exhibit this arrangement.

(Here insert Fig. 6.)

3883 In which A B is the charcoal *c c′* slips of wires *w w′* wires soldered to the copper slips. When the wires were connected with an elementary or with a compound battery the needle was deflected in the same manner as by a metallic wire. When one of the slips of copper was placed below the needle and at the same distance as before the needle was equally deflected. The needle is therefore deflected by the quantity of electricity conducted without any regard to the nature of the conducting substance.

Since charcoal, therefore, deflects the needle, it might be made to rotate about a magnet agreeably to the laws as established by the ingenious experiments of Mr. Faraday. This was accomplished as follows:

Exp. IX. A thin slip of copper having a small cup soldered on the middle and two short tubes on the end to hold pieces of charcoal was placed on the point of a needle on the pole of a horseshoe magnet, the points of charcoal being made to dip into the mercury contained in the wooden cup as in the experiment for the rotation of a wire. The charcoal was now made to conduct voltaic electricity from a battery of a hundred pair- of plate- when it revolved rapidly as a metallic wire would have done in similar circumstances.

21. The French philosophers have introduced a distinction between the current of voltaic electricity passing along a metallic conductor and that transmitted by a liquid conductor which seems to me entirely groundless. This distinction may be given in the words of Mr. Cumming in his translation of Demonferrand's Manuel of Electro Dynamics: "In the present state of science, it is perhaps expedient to consider electrical currents in another point of view, namely, as being continuous or discontinuous. The first are those which are transmitted by perfect conductors, and whose intensity varies insensibly in two consecutive instants, as in the thermo-electric or in the common galvanic circuits. When the conductors are imperfect the currents are discontinuous. For bodies of this description permit the electricity to accumulate for a certain time after which the insulating force being overcome it passes
3884 with an explosion; and if the electro-motive power continues to act there ensues a second accumulation and explosion as before, and so on successively. The distinctive character of such currents is that they are incapable of producing a deviation in the magnetic needle" (Cumming's Translations of Demonferrand's Electro Dynamics, page 116).

From the manner in which this distinction is laid down by the

French writers, I had always taken it for granted that a needle suspended above the liquid part of a conductor of voltaic electricity was feebly deflected, and should probably have remained in this belief had I not entered on the present experimental investigation.

This assertion I put to the test of experiment as follows:

Exp. X. Having cemented a glass tube about an inch in diameter and four inches long into two wooden boxes A, B, as in figure 7,

(Here insert Fig. 7.)

and filled the whole with water, I placed two plates of copper *c c'*, having copper wires soldered to each opposite the ends of the glass tube T. The wire proceeding from *c'* after extending about a foot upwards was bent towards the left at D and then made to descend at E, and pass parallel to the needle N, S, and thence to the end of a battery. The other wire *w* was connected with the other end of the battery. It is obvious from this arrangement that the effects of the electricity arranged in the cylinder of water and those of the horizontal branch of the wire above the needle would be to turn the needle in opposite directions. When the branch G, H, was further from the needle than the axis of the tube represented by the dotted line the needle was deflected in obedience to the cylinder of water; but when the wire was brought nearest the needle it was deflected in the opposite direction.

3885 When the wire was placed at the same distance from the needle as the axis of the cylinder the needle remained perfectly stationary. When a disc of zinc was substituted for one of the copper plates and the wires connected so as to form an elementary battery the needle was deflected with the same force by the column of water as by the metallic part of the circuit. Hence, it is obvious that a cylindrical column of water conducting voltaic electricity deflects the needle with the same energy as a metallic wire passing along its axis and forming a part of the same circuit.

22. To complete this part of the enquiry, I was anxious to make a hollow column of water revolving about the pole of a magnet. This was accomplished as follows:

Exp. XI. Having procured two thin hollow cylinders of wood, the one about two inches and a half in diameter, and the other about an inch and a half, I cemented the one within the other at the bottom. Two flat rings of copper were then fixed parallel to each other at the bottom and top of the cylindrical box, the space between them being for the reception of the water or diluted acid. This annular space was divided into two compartments by thin slips of wood placed perpendicularly to prevent the water revolving without carrying the box along with it. Two small metallic points were made to pass from the lower copper ring through the bottom of the box for the purpose of dipping into a cup for holding mercury. The opposite sides of the upper ring were connected by a wire, to the middle of which was soldered a metallic point to dip into a small metallic cup for holding mercury at the top of the magnet. The whole arrangement will be obvious from the simple inspection of figure 8.

(Here insert Fig. 8.)

In which the cylinder C is seen in perspective with the metallic point to dip into the mercury contained in the wooden cup
3886 which is used for the common rotation of a wire, and N, the magnet. The box is partly suspended by an untwisted thread T, so that the metallic point may not rest on the bottom of the cup on the top of the magnet, but simply dip into the mercury.

When the wire *w*, from the cup on the top of the magnet is connected with one end of a powerful battery and the wire from the wooden cup into which the metallic point dips connected with the other, the water in the box is rapidly decomposed, and the whole revolves about the pole of the magnet. By changing the poles the box and its contents are made to turn round in the opposite direction. I was now anxious to make the hollow cylinder of water revolve whilst the vessel in which it was contained remained stationary. This was accomplished by the following arrangement.

Exp. XII. Two glass cylinders were cemented into grooves in a circular piece of wood, through the centre of which the magnet was made to pass, as in the preceding experiment. The circular rims of copper were fixed as in the wooden cylinder, the breadth of the upper ring being considerably less than that of the lower. The inspection of figure 9 will render the whole obvious.

(Here insert Fig. 9.)

In which A, B, is a section of the glass cylinders N the magnet W, the wire connected with the lowest copper ring *w*, that connected with the other, and reaching to the ends of the battery; V represents a wooden vane having two vertical branches immersed in the conducting fluid and balanced on a fine point resting on the top of the magnet.

When the wires are connected with a powerful battery the water begins to revolve forming a real vortex and carrying the wooden vane along with it. When bodies of the same specific gravity as that of the fluid are thrown into it, the rotation is rendered obvious without the wooden vane. When the lower ring is con-
3887 nected with the negative end of the battery, the bubbles of hydrogen as they ascend wind around in a spiral direction till they reach the surface of the fluid.

These experiments demonstrated that the action of magnets is entirely on the electric arrangement without any relation to the ponderable substances with which it combines; and they may yet enable us to assign the cause of currents in the ocean which have not received a satisfactory explanation.

23. In examining the changes which took place in water placed between the platinum poles of a powerful galvanic battery, I was struck with the difference of temperature which I observed in the water at the two poles. The phenomena which thus presented themselves appearing to me new and highly interesting I was induced to examine the subject by careful experiments and investigation. The following arrangement presented itself and brought out new and unexpected results which seem to open a wide field for future inquiry.

Exp. XIII. Having made a small rectangular box, I divided it into three compartments by diaphragms of bladder as in figure 10.

(Here insert Fig. 10.)

In which A, B, C, are the three chambers and the box nearly filled with common water. The copper wires *w w′*, being connected with the ends of a powerful battery, the water was rapidly decomposed through the moist bladder. After decomposition had gone on for eight or ten minutes, the temperature of the water in the three cells was examined, when it was found that the temperature of the water in each of the cells had risen during the experiment, that the temperature of the water at the positive pole had risen several degrees higher than that in the negative cell; but what seemed most remarkable was the fact that the water in the
middle cell had risen several degrees higher than the water
3888 in the positive or hottest chamber. The cause of this curious
result soon presented itself.

The general rise of temperature in the conducting fluid is undoubtedly caused by the same agency which raises the temperature of a metal where performing the same office as the fluid. The difference of temperature in the extreme cells depends on the specific heats of the gases disengaged. The specific heat of oxygen is nearly the same as that of hydrogen. But there being twice as much hydrogen given off at the negative pole as oxygen at the positive it will absorb nearly twice as much heat from the water in that chamber as the oxygen does from the water in the other. The temperature of the water in the negative chamber must, therefore, be kept lower than that in the other compartment. If liquids could conduct voltaic electricity without suffering decomposition, the diameter of the whole mass between the poles would have its temperature equally elevated in every point; but the two unequal cooling processes going on in the extreme chambers occasion the striking inequality of temperature in the three divisions. But this experiment appears to me to establish another point of vast importance in the theory of voltaic electricity. If the hydrogen which is set at liberty at the negative pole traversed the fl/uid between the two poles, it is obvious it must have acquired its specific heat at the positive pole, and consequently could not have lowered the temperature in the negative cell. The oxygen, then, which is disengaged at the positive pole must have belonged to the film of water in contact with the negative pole. There appears, therefore, to be no actual transfer of the component parts of the water, but agreeably to the views of M. Grotthus, a continued series of decompositions and recompositions along the whole chain of acqueous particles between the two poles.

24. The explanation now given of this curious phenomenon receives the strongest confirmation from the decomposition of other substances besides water. When a solution of sulphate of copper
was placed between the poles of a powerful battery, and the
3889 temperature of the cells examined as before, it was found
that a much greater difference between the temperatures of

the extreme chambers took place; but the temperature of the negative chamber was now higher than that of the positive. In some of my experiments the temperature of the negative cell rose 8 or 10° above that of the positive, whilst the middle chamber was nearly of the same temperature with the negative compartment. The same striking difference was observed when a solution of acetate of lead was employed.

The cause of this change of temperature depends as in the case of water on the specific heats of the elements separated at the two poles. When a metallic salt is decomposed by the agency of voltaic electricity, the pure metal is separated at the negative pole whilst the oxygen appears at the other pole. Now, the specific heats of metals are exceedingly small. The change of state, then from the liquid to the solid which took place in the negative chamber must have raised the temperature, while no such change of state took place in the positive compartment. Hence the temperature of the negative cell must be higher than that of the positive. It is unnecessary to multiply examples. If we know the specific heats of the substances set at liberty in the extreme chambers we can tell *a priori* which of the compartments will have the highest temperature—which affords the most satisfactory evidence of the accuracy of the explanation given of this interesting phenomena.

3890 DEFENDANT'S EXHIBIT PUBLISHED DESCRIPTION OF LADIGUIN'S ELECTRIC LIGHT. W. T. F., Spec. Ex'r.

Journal of the Society of Arts, London, 1872–'3, *Vol.* 21, *August* 22, 1873.

P. 779.

The electric light.

It will be in the recollection of the readers of the "Journal" that in April last an analogy was pointed out between sunlight and the electric light, and that certain conditions were therein indicated as being most favorable to that particular development of light which would best bring out the separation of the power producing the light from the place of its manifestation. Those conditions were the employment of magneto electricity and the use of a closed incandescent conductor in an atmosphere which would not oxidize or otherwise affect the durability of the light-producing material. From the quotation from the Russian paper "Galos" which follows it will be seen that the results anticipated are even now in the course of realization, and all that practical men can do is to wish the plan the success it seems to deserve, and to wait the result of the further exhibitions of its power in London and other places more accessible to the western nations tha*t* St. Petersburg:

"On Tuesday, the 8–20 of May, a most interesting trial was made for the first time in public at the Admiralty house in St. Petersburg, under the auspices of Messrs. S. A. Kosloff & Co., the proprietors of the patent of a new system of lighting by electricity, the invention of Mr. A. Ladiguin of that town.

"Owing to the restricted space in the hall made use of on this occasion, the number of spectators was necessarily limited, but still they consisted of more than a hundred specialists from different
countries, representatives of science, honorable visitors, and
3891 many reporters, who were all deeply interested, and unanimously decided that the trial was really successful.

"Up to the present time, as is well known, the electric light has been used only for light-houses, as an electric sun illumination for signals, or on the stage where a strong light may be required without regard to cost; but thus far it has been impossible to employ it for lighting streets or houses.

"By the old method the electric spark was passed between two points of charcoal, each attached to a copper wire connected with an electro-magnetic machine.

"The disadvantages attending this mode consisted in the facts that for each light a separate machine was required and that the light so obtained, although very powerful, was impossible to be regulated, besides being non-continuous, owing to the rapid consumption of the charcoal points from exposure to air.

"All the difficulties Mr. A. Ladiguin has tried and apparently overcome most successfully.

"By his newly invented method only one piece of charcoal or other bad conductor is required, which being attached to wire connected with an electro-magnetic machine is placed in a glass tube from which the air is exhausted and replaced by a gas which will not at a high temperature combine chemically with the charcoal. This tube is then hermetically sealed, and the machine being set in motion by means of a small steam engine, the charcoal becomes gradually and equally heated, and emits a soft, steady and continuous light, which by a most simple contrivance can be strengthened or weakened at the option of those employing it; its duration being dependent solely on the electric current, which of course will last as long as the machine is kept in motion.

"Taking into consideration the fact that one machine worked by a small three-horse-power engine is capable of lighting many hundreds of lanterns, it is evident what an enormous advantage and profit could be gained by the illumination of streets, private houses,
public buildings and mines with the new electric light. In
3892 the latter it must prove invaluable, as no explosion need ever
be feared from it, and these lanterns will burn equally as well under water as in a room.

"Without mentioning the many advantages this mode of illumination has over gas, which by its unpleasant odor and evaporation is slowly poisoning thousands of human beings, and from which explosions are frequent, we can state that by calculations made this electric light can be produced at a fifth of the cost of coal gas.

"We hope shortly to place before the public more complete particulars, as well as reports of further experiments which are proposed to take place in Vienna, Paris and London."

See the Russian paper "Galos," No. 129, of May 11–23, 1873.

3893 DEFENDANT'S EXHIBIT VIOLETTE PAPER. W. T. F., Spec. Ex'r.

American Journal of Science and Arts, Vol. 16.

G. P. Putnam & Sons, New York, 1853 (p. 270).

Overheated Steam Applied to the Carbonizing of Wood.

For several years past overheated steam has been used in numerous industrial operations, and we may say generally that it may be applied in all processes in which a temperature between 100° and 500° C. is required. Among these processes is the extraction of wood spirit, the continuous baking of bread, the preparation of sea biscuit, the drying of wood, the preservation of meats, the extraction of volatile substances insoluable in water, the purification of fatty acids by MM. Leplay and Dubrunfaut, the extraction of the mercury from the residues of zinc amalgam by M. Violette, and finally the carbonizing of wood by the same chemist.

M. Violette is a member of the commission on powder and saltpeter, and in this situation he has turned his attention to the ingredients of powder, the manufacture of which still admits of much improvement. The charcoal employed in this manufacture is of a quality intermediate between wood and ordinary charcoal; it is called red charcoal (charbon roux), and is produced at 300° C.; at a higher temperature it becomes black charcoal, and at a lower the carbonization is incomplete.

By the old process of heating in closed cylinders, 10,000 kilogrammes of wood furnish 2,000 kil. of black charcoal, and 1,300 of red. The new process with steam yields a better article in larger quantity for 10,000 kil. of wood give 4,000. The wood immersed in the vapor is readily carbonized, and as it is easy to regulate the
temperature of the vapor charcoal may be obtained of a con-
3894 stant and uniform character. It has some use since, though
overheated steam was first adopted in this process by M. Violette, and now the red charcoal, before employed only for the finest powder, is in general use for the cheaper kinds, so simple and certain is its production by means of steam.

M. Violette communicates to the academy some new results. He shows that the change to charcoal takes place differently with different woods, and that the products of the same temperature differ in elementary constitution. Exposed to moist air the charcoals absorb more water the lower the temperature to which they are exposed and the —— is of their power of conducting heat and electricity. Charcoal made at 1,500° C. conducts much better than the charcoal of gas retorts, and serves perfectly for electric illumination. The density increases in the same proportion. When lighted charcoals remain ignited for a time, which decreases as the temperature of carbonization increases. The charcoal made at 260° C. burns more easily and longer; that made between 1,000° and 1,500° C. will not ignite or burn.

The most inflam-able of all charcoals is that of an agaricus. It takes fire spontaneously at 300° C. Other charcoals prepared at the temperature 300° C. take fire in the air spontaneously between 360° and 380° according to the wood that is afforded, though the charcoals of the lighter woods burning the most readily.

When charcoals are mixed with sulphur they are inflamed at a temperature much below that required when alone; the mixture of the two prepared between 150° to 400° C. is wholly consumed at 250° C. On the contrary, when the charcoal employed has been prepared at 1,000° or 1,500° C. only the sulphur burns.

To decompose saltpeter, the charcoals require a higher temperature; and heat of 400° C. is needed for charcoals prepared between 150° and 432°, and a red heat for those made between 1,000° and 1,500°.

Sulphur decomposes saltpeter at a higher temperature than charcoal requires, viz., at 432°. The sulphur alone inflames in common air at 250° C. and not at 150°, as stated in treatises on chemistry.

3895 The deflagration of powder takes place at 250°, but this combustibility varies with the charge and the size of the grain. The powder in grains burns between 270° and 320°, while powder pulverized burns between 265° and 270°.

In view of the facts M. Violette concludes that it is necessary to revise the charges employed, taking into consideration the actual position of the charcoal. Trials made with this in view upon hunting powder with charges calculated according to the actual position of the charcoal have given a range much beyond the standard rate obtained with the ordinary powder.

3902

Edison's Exhibit No. 7.

Extracts from Records of Experiments, Book No. 85.

"All pumps give a great deal of trouble at F where a contraction is made so that the air in G may be forced out from H.

" B. This stop-cock placed too far from the main reservoir so that the tube near it caught air. This could be worked out by letting the Hg work up and down. The McLeod should not be used until a high vacuum has been attained. For if this has not been done the Hg sticks in the side tube. Last evening a vacuum was obtained so that the spark jumped five inches outside of the tube rather than across $\frac{1}{4}$ inch in vacuum. The changes in vacuum were extremely rapid from green to preventing a small spark in a few seconds and then in a few minutes to stopping the large spark. The finely divided copper and sulphuric acid may have had a strong influence on this F, the tube contracted here so that a pressure can be obtained in G to drive the air out through the stop-cock H.

"The enlargement of the tubes at L and L^1 is a mistake, as a bubble of air collects here and is drawn up into the pump. Making stop-cock D with tube to left inclined upwards may be a mistake, as the Hg collects above the cock and stops the Geissler. Pure black rubber tube placed inside of white rubber to prevent soiling Hg."

3903 & 3904 EDISON EXHIBIT NO. 8.

(New York Sun, December 22d, 1879.)

Electrician Sawyer's Challenge to Electrician Edison.

If a party possesses an interest in something that he considers valuable, he is not very likely to part with it, especially if it be something in the line of electric lighting, where what may nominally be $1 may really be $1,000. Therefore, when Mr. Edison sells out all his interest in his electric light there is a reasonable chance for a suspicion that he considers his invention worth very little.

Mr. Edison's reputation before the public is founded upon the newspaper publications about: 1. The quadruplex telegraph; 2. The telephone; and 3. The phonograph.

As to the quadruple telegraph, I may say that it was an adaptation of the French and German systems. When Mr. Edison took hold of the 4-plex there were already known five systems of 2-plex, three of 4-plex, and three of 6-plex and 8-plex.

The 4-plex of Edison was a failure. A modest young gentleman, assistant electrician of the Western Union Telegraph Company, whom I have not seen for several years (Mr. Gerritt Smith), made it a success, and some day he will get the credit for this invention; for he, and not Edison, is the genius in this case.

As to the telephone, Mr. Edison is not the inventor. Andrew Graham Bell is the inventor of the telephone.

As to the phonograph, which really made Mr. Edison's reputation, it is of no earthly value, and the manufacture by Bergman has practically been dropped. The real inventor of the phonograph will never be known, in all probability, for I understand that Mr. Edison anticipates a Western man but three days in priority of invention.

3905 Now, all that remains for Mr. Edison is electric light. He is going over the same ground that Bouliguine, Lodygreine, Kosloff, Koun, Starr King, myself, and others have traversed—first, iron; second, platinum; third, carbon in different shapes. And Edison has failed, in my opinion. To show that I mean what I say, I deny every one of his allegations made at the Saratoga convention of the American Society for the Advancement of Science, and, specifically, I challenge him:

First. To maintain a vacuum in his lamps.

Second. To run his carbonized-paper lamp three hours. (In practice, in a perfect vacuum, it will last twenty minutes.)

Third. To consolidate platinum by heating electrically in the Sprengel vacuum, as he claims.

Fourth. To prove that his dynamo-electric machine develops not ninety, but even forty-five per cent. of the feet pounds applied to it.

Fifth. To show that he can obtain a light of twenty-five candles from platinum with less than three horse power.

Sixth. To show that platinum or iridium will not disintegrate in twenty hours' actual running.

Seventh. To prove that with his carbonized-paper lamp he can obtain two lights of ten candles each per horse power.

Eighth. To show that the effect of the oxide of magnesium is to harden his wire, and make it more refractory.

And I further allege that all Mr. Edison's statements are erroneous, and I offer $100 as a prize for him to prove each of the above allegations. Let him run one of his lamps three hours, and the public will be satisfied that I am correct.

W. E. SAWYER.

DEFENDANT'S EXHIBIT NO. 25. W. T. F., S. E.

EDISON'S EXHIBIT NO. 25. W. H. M., Notary Public, N. Y. Co.

Mr. Edison Challenged by Mr. Sawyer.

To the editor of the Sun.

SIR: Notwithstanding the assertion that one of Mr. Edison's electric lamps has been running for 240 hours, I still assert, and am prepared to back up my assertion, that Mr. Edison cannot run one of his lamps up to the light of a single gas jet (to be more definite, let us call it twelve candle power) for more than three hours. To be still more definite, I offer to Mr. Edison, at 226 West Fifty-fourth street, in this city, an opportunity to prove what he says. From the private residence in that street wires are run to a circuit of 1,000 feet Mr. Edison shall have every facility; he shall use my wires; he shall have any dynamo machine or other generator of electricity he may prefer; and all I ask is that the power of his light shall be measured by a photometre; that, once in place, it shall not be interfered with; and that a committee of gentlemen, preferably nominated by the editors of the New York press, shall be present and certify to the facts of the test.

Furthermore, I will place one of my lamps side by side with Mr. Edison's; it shall be run at the power of twenty-five candles; it shall outlast the entire forty lamps at Menlo Park run at the power of twenty-five candles; my lamp to stand as it is put up, and Mr. Edison to put up a fresh lamp as fast as the preceding lamp shall have burned out.

3914 I am anxious for this test; and if Mr. Edison has really run one of his horseshoe lamps 240 hours he will not refuse to accept my offer, for he will be treated with the utmost courtesy, and shall have everything his own way.

I adhere in every particular to my original challenge to Mr. Edison.

W. E. SAWYER,
78 Walker Street, New York.

Jan. 4.

The Sun, Monday, January 5th, 1880.

3915 Letters patent, for fifteen years, taken out July 12th, 1876, by Mr. Gauduin (Octave), of Paris, Rue de la Roquette, No. 130, and which was granted to him by order of the minister of agriculture and commerce, under date September 16th, 1876, for a carbon intended for the manufacture of utensils of chemistry and physics, etc.

Letters patent No. 113,706.

Certain utensils of chemistry and physics, like the crucibles intended for the reproduction of precious stones or for chemical laboratories, the pencils intended for the production of electric light, etc., should be made of chemically pure carbon. Now, the dust of retort carbon ("retort charcoal"), though containing but a small proportion of foreign matters, is not sufficiently pure for these uses, and its employ presents difficulties. The washings with acids or with alkali- to which the carbonaceous (coaly) matters can be subjected, with the object of taking out the impurities which they contain, are costly and insufficient; soot is sufficiently pure, but high priced and difficult to use, and I had to look for another source of pure carbon for the economical fabrication of these objects.

I manufacture pure carbon at a low price by decomposing, by heat, in closed vessels, dry or liquid pitch, tar, rosin, bitumen, natural or artificial essences and oils, organic matters capable of yielding sufficiently pure carbon after their decomposition by the heat. The apparatus which I employ to effect this decomposition are closed retorts or crucibles of cast iron, iron, refractory clay, but preferably of graphite (plumbago). They are arranged in a furnace capable of heating them to clear red heat. The upper part of the retort is furnished with two tubes, the one for the escape of the gases and volatile matters, the other for the introduction of the raw material.

(Here follows diagram marked p. 3917.)

Figure 1 will explain this arrangement. The volatile products of the decomposition may be conducted under the grate of
3916 the hearth and burned to heat the retort, but it is more advantageous to lead them into a condensing chamber, then into a serpentine ("serpentine pipe") of copper, lead, tin, or pottery, and, after condensation. to collect the tar, oils, essences, and carburets of hydrogen, which are produced by this operation. I utilize these different products for the manufacture of my carbon utensils, and, as they are not met with in the trade in a state sufficiently pure for my industry, they are exceedingly useful to me.

It is indispensable to avoid (using), for condensing or preserving these products, vessels of iron, cast iron, zinc, or other materials susceptible to their attacks, for their whole value lies in their purity.

Whatever the raw material is that is used in the manufacture of my carbon, the decomposition by heat may be operated slowly or quickly, according to the nature of the secondary products which I wish to obtain.

To operate slowly I fill a retort two-thirds full and I heat it gradually to clear, red heat, avoiding, as much as possible, the swelling (puffing) of the material. To operate rapidly, I first heat the empty retort to a good red heat, and I cause the raw material to arrive at the bottom of the retort in small portions, either in a small stream, if it is liquid, or in small pieces if it is solid.

The slow distillation produces more tar, heavy oils and little gas; the quick distillation produces more light essences and gas. I employ the one method or the other, according to the products which I need.

When the raw material has been suitably selected, there remains in the retort pure carbon, more or less compact; I pulverize it as fine as possible, and I agglomerate it, either alone or mixed with a certain quantity of soot, by means of pure carburets of hydrogen obtained as secondary products. Thus prepared these bodies are completely free from iron and are greatly preferable to those met with in trade, not only for the agglomeration of the carbon, but also for the impregnation of the manufactured articles, an operation which, while stopping up their pores, introduces into them oxide of iron when it is performed with the products of commerce.
3918 Nevertheless, I reserve the right of exclusive use of carburets of hydrogen, pitch, tar, oils or essences of coal, etc., found in commerce, to agglomerate or impregnate the objects which I manufacture, as appears from the certificate of addition to my patent No. 87569.

The articles made of agglomerated carbon are, taking the same kind of carbon, more combustible as they are more porous, and more porous as they have been molded at less pressure. I use molds of bronze, cast iron or steel capable of resisting the greatest pressure of a strong hydraulic press. Figure 2 shows a crucible mold, a simple examination of which will cause the mechanism to be understood.

Although the draw-plate ("draw-plate" is a literal translation of the term filière) or molding apparatus, long used in the manufacture of the pencils of carbon, soot, plumbago (graphite), etc., intended for writing or drawing, might serve, without any modification, for the manufacture of pencils for electric lighting, I have made certain improvements in this apparatus, the exclusive use of which I desire to reserve. Instead of causing the pencils to go out from top to bottom, going vertically, I place the — (there has evidently been some omission here on the part of the copyist in France) or the orifices of the mold on the side, and in such a manner that the pencils pass out, forming with the horizon a descending angle from 20 to 70 degrees. They are guided along their whole length by tubes or channels (grooves). This arrangement enables one to empty out all the material contained in the mold without interrupting the work, and, as the pencils are constantly supported they no longer break under their own weight, which often happens when they pass out downwards. It is above all useful in the manufacture of thick and long pencils intended to be used as positives in electro-chemical decompositions; these carbon positives replacing advantageously the platinum.

Figure 3 represents a pencil mold with outlet pipe on the side.

Descriptive account accompanying:

The certificate of addition, taken out 12 June, 1877, by Mr. Gauduin, represented by Mr. Rouart, in Paris, Rue Oberkampf 151, and relating to letters patent, for 15 years, taken 12 July, 1876, for a carbon intended for the manufacture of utensils of chemistry and physics, etc. * * * The said certificate of addition being granted, by order of the minister of agriculture and commerce, on the 13th September, 1877.

Certif. of Add. to Let. Pat. No. 113,706.

(Here follows diagram marked p. 3920.)

Fig. 1 represents the vertical section, and Fig. 2 the plan of a tubular furnace permitting the baking ("burning"), continuously, of pots, (crucibles), pencils for electric lighting and for electro-chemistry, and other utensils of carbon which I manufacture.

It is composed of a frame-work of bricks (iron bands) held on the exterior by strong iron-work. The tubes G, G, of refractory material, traverse it through and through and are closed at the two ends only by clay plugs, which can be easily removed for the charging and discharging (placing and removing) of the objects to be baked.

These are enclosed in cylindrical boxes of sheet iron represented in Fig. 3. They can glide easily in the refractory tubes. When the boxes and their contents have attained a sufficient (degree of) temperature, they are taken from the tubes and replaced by others. The charging and discharging are thus performed very easily, without stopping the working of the furnace, and without a noticeable cooling off.

H H, draught chimney.

J J, hearth.

K, grate.

L, ash pit.

3921 It is evident that the tubes might be arranged in a furnace either completely vertical or completely horizontal, with no great inconvenience. So also the relative dimensions might be changed, within certain limits. What I consider as my property is the idea of heating tubes in any suitable furnace, and baking in them objects of carbon, enclosed or not in movable boxes.

I have found that a mixture of albumen and sugar, dissolved in water, in suitable proportions, can communicate certain useful properties to the objects of carbon. I reserve for myself the use of this syrup for agglomerating and impregnating the utensils of carbon, crucibles, pencils, etc. The albumen may be replaced by the other albumenoid substances.

The drying of the objects formed may be performed in the open air or in a suitably heated drying chamber. These means are rather slow. It is more expeditious to enclose the objects in a hermetically closed receiver, in which a vacuum can be produced by means of a pneumatic pump. It is well to intercalate, between the receiver and the pump, a vessel containing lime, chloride of calcium, or other materials capable of absorbing the vapors as they are produced.

To recapitulate—

I claim by the present certificate of addition:

1. The exclusive use of tubular furnaces for the baking of crucibles, pencils for electric lighting and for electro-chemistry, and other utensils of carbon.
2. The agglomeration and impregnation of the different varieties of carbon by a syrup of albumen and sugar.
3. The rapid drying of the manufactured objects by the employ of the vacuum, either alone or aided by materials capable of absorbing the vapors emitted.

Paris, 12 June, 1877.

(Signed) OCTAVE GAUDUIN.

3922 Certificate of addition, taken out April 7th, 1877, by Mr. Gauduin, Octave, at Paris, Rue de la Roquette 130, and which relates to letters patent, for fifteen years, taken out 12th July, 1876, for a carbon intended for the manufacture of utensils of chemistry and physics, etc., . . . the said certificate of addition granted by order of the minister of agriculture and commerce, on June 22d, 1877.

Certificate of Addition to Letters Patent No. 113,706.

I have succeeded in giving to my carbon the definite form which it is to preserve, and in simplifying considerably the moulding and the forming of the objects which I manufacture by the following process:

I form the crucibles, vessels, pencils for electric lighting or for electro-chemistry, etc., with dry wood, suitably selected, by all the methods proper to working in wood. I convert this wooden object into a hard and compact carbon, conserving its primitive ("original") form by drying it suitably, impregnating it with tar, pitch, bitumen, rosin, essences and oils of coal, any carbon of hydrogen, sugar, caramel or other matter possessing analogous properties.

I distil it slowly so as to expel the volatile bodies; I impregnate it anew and redistil it as many times as necessary, and finally I heat it to a high (degree of) temperature in a reductive atmosphere.

For objects which need a very pure carbon, like the pencils for electric lighting, it is good to wash the carbon object when it is still porous with acids and alkalies, so as to dissolve the impurities which it may contain, and to rinse it afterward in plenty of water.

I can also heat it to red heat and submit it during a certain time to the action of chloride of carbon, hydrochloric and hydrofluoric gaseous acids. I finish by vapors of carburet of hydrogen capable of stopping the pores by depositing carbon in them.

3923 I also manufacture articles of carbon from cotton, hemp, flax, cellulose in any state, kneaded and impregnated with pitch, tar, etc., and formed so as to give it the desired shape. I finish them as if the object were of impregnated wood.

To recapitulate:

By the present certificate of addition I claim the manufacture of crucibles, pencils for electric lighting and electro-chemistry, vases and utensils of any kind, by converting the wood and the cellulose into carbon by the means described above, or by analogous means.

Paris, 7th April, 1877.

(Signed) OCTAVE GAUDIN.

Comptes Rendus LXX, 605; *Paris*, 1870.

Action of carbon sulphide and carburetted gases upon wood charcoal.

M. SIDOT.

In a preceding work I showed that carbon sulphide was decomposed by charcoal, that the latter increased in weight and that sulphur was liberated. While pursuing those researches I examined how carbon sulphide acts upon certain organic bodies of vegetable or animal origin.

Into a tube of porcelain I introduce small bundles of wood, over which I pass cold vapor of carbon sulphide, so as to expel all air from the tube. This result obtained, I heat the tube slowly and gradually to a red heat, for about one hour.

After cooling we find in the tube rings of a carbon different from ordinary carbon in physical properties. The essences of the most divers wood, ash, box, hornbeam, lilac, elder and cork may give rise to this new carbon.

What particularly distinguishes it is its sonority, like that of bodies called the most sonorous, such as steel, silver, alumin-
3924 ium, glass, etc. I have the honor to submit to the eyes of the academy some specimens of these sonorous carbons.

When we suspend them by a string and strike upon them, they give a metallic sound.

Wishing to obtain a sonorous instrument with this carbon, I turned a bell of ash, and I submitted it to the action of carbon sulphide after the process just described. This piece of ash became a bell, which also I present to the academy; it gives a sound comparable to that of a metallic bell of the same diameter. I conclude that it would be easy to reproduce a gamut with a xylophone of carbon, and to construct a harmonicon of carbon bells.

Very hard woods seems to give the purest and most harmonious sounds.

These same carbons, distinguished so clearly from ordinary ones, by their elasticity, also differ widely by their great conductivity of heat and electricity. I think they might replace the carbons in the Bundsen cell.

The pencils made of them give an electric light far more intense than the light obtained with carbons from gas retorts.

This carbon conductor heats up like a metal and becomes progressively incandescent in the whole mass, without igniting at one point, like ordinary carbon; it cools as soon as it is removed from the fire. It may be characterized from a point of view of conductivity as wood charcoal transformed into coke.

I have obtained similar results from flax, hemp, cotton paper and silk.

The carbon obtained from wood has a metallic lustre, but this lustre is only superficial.

It has a greater density than wood carbon.

It does not perceptibly absorb gases. I should mention in this connection, that by heating the wood to a high temperature in crucibles filled with finely pulverized cinders, we obtain likewise a carbon deprived of absorbent qualities, and besides a good conductor.

3925 Carbon sulphide is not the only agent for this remarkable change of wood into sonorous conductive carbon. Wood spirit, hydrocarbons, etc., similarly change wood into elastic conductive carbon.

More than this; I assured myself that by passing vapor of methylic alcohol over wood heated red, this vapor was decomposed, and the interior walls of the tube were carpeted with a very singular carbon at the same time.

This carbon, in fact, presents itself in the form of filaments, one centimetre in length, constituting a kind of silky and frothy coke of a silvery white. These filaments seem to be formed of small juxtaposed balls.

CONSOLIDATED E. L. CO.
vs.
McKEESPORT L. CO.

DEFENDANT'S EXHIBIT PROF. CROSS' REPORT OF 1881 (No. 1). April 20, 1887. W. F. F., S. E.

MASS. INST. OF TECHNOLOGY, BOSTON, *June 23d*, 1881.

F. H. Betts, Esq.

DEAR SIR: I have examined the American patents and the various works on electric lighting with reference to the matter of the resistance of incandescent lamps previous to the date of Mr. Edison's patent. I have not yet looked at the English patents, preferring not to delay longer before writing to you. I will look them over to-morrow or next day.

From all the statements that I can find, or calculations that I can make, based upon these statements, I should say that the lamps previous to Mr. Edison's patent had a resistance of not over five ohms, and generally much less than this. I infer this from the statements made regarding the size of carbons, in which they are called "pencils," "small rods," &c.; also from the measured dimensions as given in the drawings of said lamps. In Sawyer's book on lighting by incandescence, p. 90, the resistance of his lamp is stated to be twenty-five one-hundredths ohms.

The only statement regarding higher resistance is in Sawyer's book, and also in his patent No. 205,303 (distribution of lamps), the resistance of lamp is called 10 ohms when hot, "practically *nil*" when cold, "practically *nil*" being, I suppose, one-quarter ohm.

But the effect of heat on carbon (unlike its effect on metals) is to diminish its resistance, this diminution being, according to Mathieson, about 12 per cent. when the carbon is raised to incandescence. The increase of resistance from heating of the metallic conductors could not be great in any lamp that could be practically used, so
that I am inclined to think that the number, 10 ohms, is
3927 stated at a venture. Mr. Edison could probably solve this
question immediately from his practical knowledge.

By the way, can the Sawyer patent, No. 205,303, for distribution of lamps, be held? The principle on which any resistance should be arranged for maximum effect has been familiar to every scientific man for the last forty years.

Compared with all these actual resistances (up to 5 ohms), that of the Maxim lamp is certainly "high" beyond a question. The only point regarding which an objection could be made is that one hundred ohms is the lowest resistance mentioned in the Edison patent. On the other hand, Mr. Edison here describes for the first time (if I am right) a process by which a carbon filament can be made practically. No carbon rod of, say 20 ohms resistance upward, could readily be made to emit light by incandescence by any current that could be practically and economically employed. At least this, I should judge, to be the case. Hence, is not Mr. E. justified in claiming that even 20 ohms would be a high resistance. If only 5 ohms as a maximum were used before, if Mr. Edison's process is a new one, giving the possibility of making high-resistance carbons, it seems to me that even though the ratio of 5 to 20 is the same as 20 to 100, the claim can readily be held. Here your suggestion that the possibility of using lights in multiple arc is an index of their high resistance in the terms of the patent, might be available. But the Maxim lamp has a resistance of 40 ohms.

As to the sealings of the Maxim lamp. I have entrusted an analysis of the blue and black substances used in sealing to a competent chemist, who will give me his report by the close of this week or first of next. Meanwhile, I will say that from a careful examination of fragment of the material after cutting it, we are pretty well convinced that it is a glass or an enamel. The blue is probably colored with copper, the black with iron (?) and manganese. The chemist thinks it may be a borax glass for easy 3928 fusion. He thinks the only possible claim that could be made is that it is "enamel," which is a kind of glass. As to this last point, I have not looked up the chemistry of glass, thinking it hardly necessary just yet. The Encyclopedia Britannica and Appleton's Encyclopedia both speak of enamel as a glass, and the latter classifies it under the kinds of glass! The conducting wires are sealed into the glass, as in Edison's lamp. It seems to me, then, that the Maxim lamp and Mr. Edison's are substantially the same thing.

I believe that I have touched upon all the points mentioned by you. I will write again as soon as I have heard from my chemist.

I am yours very truly, CHAS. R. CROSS.

(Endorsed.)

DEFENDANT'S EXHIBIT PROF. CROSS' REPORT of 1881 (No. 2). April 20, 1889. W. F. F., S. E.

BOSTON, *June 24th*, 1881.

F. H. Betts, Esq.

MY DEAR SIR: I have to-day looked over the various English patents relating to electric lighting by incandesence. I find nothing to change my opinions as expressed in my letter to you. The only light about whose very low resistance there is any question is Werdermann's, but in this incandescence proper as distinct from a very minute voltaic arc is distinctly disclaimed.

Very truly yours, CHAS. R. CROSS.

(Endorsed.)

17. 19074. 17.

JUNE 24, '81.

C. R. Cross to F. H. Betts: Have examined English patents and find nothing to change conclusions arrived at in letter of 23d inst.

3930 (*French Patent Records, 2d Series, Vol.* 16, *p.* 223.)

4606.

Patent for fifteen years.

Dated Jan. 31st, 1849.

To Mr. Le Molt, of Paris.

For improvements applicable to the apparatus suitable for electric lighting.

A first improvement relates to the elements of the pile, another to a double movement which is given to the carburetted material that serves for the production of the electric light.

One of the elements of the pile is a carbonized material, in the form of a cylinder or of a plate, more or less thick and hardened by compression. This material may be composed of—

Ashes of gas retorts..................................	4	parts.
Liquid tar..	1	"
Ashes of retorts..	2	"
Charcoal...	2	"
Liquid tar..	1	"
Coke...	2	"
Tar of bitumen...	1	"

All these substances, pulverized, sifted, and mixed with the liquid tar, are brought, by a powerful trituration, to the state of a hard and consistent paste, and to this paste any desired form is given, by compression and in a mould; then it is covered by a thick syrup of sugar or molasses. These moulded pieces are placed in a retort, almost closed, and which is gradually raised to the temperature of a high furnace; after twenty or thirty hours they are withdrawn to be used.

The inventor has had the idea of galvanizing the carbon element, that is to say, of covering it with a coating of metal so as to connect the two carbon and zinc elements by a metallic handle.

On plate XXIX, Fig. 1, may be seen a carbon element and 3932 a zinc element, connected by a metallic handle.

The metallic elements of the pile are covered with a varnish which preserves all the non-acting portions of the elements from oxidation; copal varnish will suit very well.

(Here follows diagram marked p 3931.)

The vessels containing the acid liquors which are to act on the elements have curved sides, as shown in figure 3, so as to avoid the projection of the liquids outside of the vessels.

Figure 5 shows the arrangement of the element in the vessels.

1, carbon element;

2, porous vessel filled with nitric acid;
3, zinc element;
4, exterior vessel filled with sulphuric acid, more or less diluted.

As electrodes, the inventor employs any carbonated matter in the form of disks. The two disks are kept a suitable distance apart and turning on metallic axis placed in communication with the poles of the generating apparatus. At each turn the two disks approach each other a little so that, on account of the part that is burned, they remain constantly at the same distance.

Figure 4 represents an apparatus of rotation and of joining combined.

A, A, A, wheels, with pulleys and grooves of metal, fixed to the carbon disk, and serving to give them a rotary movement with the aid of the two endless chains, C, C.

B, B, axis of the carbon disk.

D, insulating materials.

E, E, contacts, one of them with roller, to facilitate the approaching of the disks.

F, double approaching wheel with eccentric rims. This is also a toothed wheel, causing the disks to turn.

3933 *Certificate of Addition.*

Dated July 24th, 1849.

This addition consists in employing a metallic wire placed in connection, at its two ends, with the conductors ending at the poles of the battery, and brought to a very high degree of incandescence, which produces an illumination. This wire is usually of platinum or of iridium, arranged in more or less drawn-out spirals, and admitting, besides, of any other arrangement.

Certificate of Addition.

Dated 14th September, 1849.

For carbon elements, charcoal alone may be used, or coke mixed with tar.

3934 COMPLAINANT'S EXHIBIT SCIENTIFIC AMERICAN ARTICLE No. 2.

Published in the "Scientific American," in New York, on December 7, 1878.

The Sawyer-Man Electric Lamp.

The practical usefulness of the electric light for illuminating open spaces and wide areas has been amply demonstrated by the various devices for using the electric arc already widely employed. Hitherto, however, it has not been found economical, or even possible, as we understand it, to construct a lamp or candle, based on the electric arc, that would answer the requirements of ordinary, domestic and industrial lighting, where a moderate amount of light, well distributed, easily manageable, and of perfect steadiness and softness is needed. The electric arc seems, from its very nature, to present insuperable obstacles to the economical production of a large number of small lights in a circuit; in other words, such lights as we require in our dwellings, offices, factories, shops and the like. And if there were no other means of obtaining light from electricity, the probability of the displacement of gas by it for the purposes of general illuminating would hardly be worth considering.

The production of light through the incandescence of a pencil of carbon or metal, forming part of an electric circuit and highly heated by its internal resistance to the passage of the electric current, offers an entirely different field for exploration; and though it has long been apparently closed by the failure of early attempts to obtain an electric light by such means, the achieved success of Messrs. Sawyer and Man, not to speak of the reported success of Mr. Edison, clearly indicates that this is the line along which the practical solution of the problem of household illumination by electricity is to come. The lamp, to be described further on, lacks
3935 only the practical demonstration of its economy by protracted
use on a large scale, to compel acceptance as a successful solution of the problem.

So long ago as 1845, an American inventor, Mr. King, patented here and in England a lamp (said to have been invented by J. W. Starr) involving this principle. His light was produced in a vacuum, to prevent the oxidation of his incandescent carbon or metal, and was extremely promising for its beauty, brilliancy and steadiness. But it failed to be permanent and economical from various defects and deficiencies, some of which have been removed by the increased power and economy of modern dynamo-electric machines, and by recent advances in the art of subdividing the electric current, but the most of them by the inventions and discoveries covered by Messrs. Sawyer and Man's patents.

The economical division of the current, or more correctly the light produced by a single current—popularly believed to be very difficult if not practically impossible—has been successfully worked out by several American investigators. As long ago as 1875, Mr. Moses G. Farmer, now electrical superintendent of the U. S. Naval torpedo station, at Newport, R. I., subdivided the electric current produced by a small machine, into forty-two different branches, putting a light to each branch. Mr. Sawyer's system appears to be able to do the same indefinitely through the maintenance of a uniform resistance throughout the circuit and equal resistances in the several parts of the circuit, as will be shown further on.

The adaptability of this form of electric lighting to the needs of household illumination is indicated in Fig. 1. The light produced is pure, strong, and yet soft, like sunlight. It is, moreover, steady and cool. It is not influenced by air currents; and it does not vitiate the air by poisonous products of combustion, nor by withdrawing the vitalizing oxygen. The lamp takes up less room than

the glass shade of a gas jet, and no more than the chimney of an oil lamp. To a limited extent, also, it is portable, and may be used as a drop light. The general appearance of the lamp is
3936 shown Fig. 2 (page 354). The light is produced by the incandescence of the slender pencil of carbon placed as shown in the engraving. The light-giving apparatus is separated from the lower part of the lamp by three di-phragms, to shut off downward heat radiation. The copper standards lower down are so shaped as to have great radiating surface, so that the conduction of heat downward to the mechanism of the base is wholly prevented. The structure of the base, full-size, is shown in Fig. 3 (page 355). No detailed description of this portion will be required, further than to say that the electric current enters from below, follows the line of metallic conduction to the "burner," as shown by the arrows, thence downward, on the other side, connecting with the return circuit. The light-producing portion is, of course, completely insulated, and also sealed at the base, gas tight.

A fatal defect in all previous lamps depending on incandescent carbon has arisen from what has been called the "vaporizing" of the carbon. This Mr. Sawyer holds to be an absurdity, since the carbon is not even fused. The wastage of the carbon in mercurial vacuums, and in atmospheres of compound gas, is due, he holds, to chemical decomposition. Many gases, indifferent to carbon at ordinary temperatures, attack it destructively at temperatures obtained in the electric lamp; and the process is continuous, the carbon taken from the burner being redeposited on the glass case, and the gas left free to continue its depredation. Mr. Sawyer claims to have overcome this difficulty by his method of charging the lamps with pure nitrogen, and by providing for the fixing of any residual oxygen left in the lamp. In this way an unwasting carbon is secured. Another stumbling block on which other workers in this field have come to grief, has been the crumbling or disintegration of the carbon burner, due to sudden heating when the lamp is lighted. This is avoided in the Sawyer-Man lamp by an ingeniously devised switch, shown in Fig. 4. By this means it is impossible to turn the current on or off suddenly, to the disruption
3937 of the carbon. This, however, is not the only nor the chief advantage of the switch. It is, indeed, the key to the entire problem, the indispensable condition, Mr. Sawyer holds, of practical electrical distribution.

It is well known that an electric current will exactly and readily divide among circuits of equal resistance. Accordingly, if the resistance of a subcircuit be maintained constant, no matter what may be going on it, whether a lamp is not lighted at all, or lighted to a mere taper, or to any intermediate stage up to full brilliancy, it is obvious that no other lamp or lamps in that circuit will be affected. The operation of the switch, in securing such uniform resistance, is shown in the accompanying diagram, Fig. 5 (page 355).

The lamp has, let us say, a resistance of 0·95 of an ohm. Therefore if one lamp is out there should be a resistance of 0·95 of an ohm in its stead This is the shunt resistance, B. The current enters at the " + " point, and leaves at the " — " point. The contact piece, A, bearing upon the two studs 1, 1, all the current passes out by way of B. When A is moved to the studs, 2, 2, the current divides, $\frac{1}{4}$ going through the lamp, the other $\frac{3}{4}$ by way of B, and the resistance of the combined circuit is $0{\cdot}31\frac{2}{3}+0{\cdot}95=1{\cdot}26\frac{2}{3}$ in the shunt; and $1.9+0{\cdot}38+25\frac{1}{3}+18\frac{2}{21}+0{\cdot}07\frac{5}{12}+0.06\frac{1}{3}+$ (the lamp) $0{\cdot}95=3.8$. The resistance of the circuit is, therefore, $\frac{1{\cdot}26\ 2{\cdot}3\ 1/3{\cdot}8}{1{\cdot}26\ 2{\cdot}3+3\ 8}=0{\cdot}95$ of an ohm, and so on. In short, the resistance of the cirucit is constant at 0.95, no matter what may be the change in the proportion of the current given the lamp, as may be seen by making the required calculation for each pair of studs. The varying resistances required to give the best effect have been worked out by practical trial. The effect of $\frac{1}{4}$ the current through the lamp is to make the carbon a dull red. On studs 3, 3, one-half the current passes through, and the carbon becomes a bright red. On studs 4, 4, the lamp gets $\frac{5}{8}$ of the current and becomes white hot. On 5, 5, the lamp gets $\frac{3}{4}$ of the current, and begins to assume the intense limpid incandescence of the sun; and the light increases rapidly with subsequent changes until the whole current goes through the lamp.

3938 Thus it is seen that the greater part of the illumination is the product of a small part of the current. When the light is well on, a very slight increase in the current increases the light enormously. It is here that the great loss occasioned by dividing a fixed current among several lamps finds its explanation. A current that suffices in one lamp to produce a light, say of 100 candles, will, if divided between two lamps, give in each perhaps no more than ten candles, or even 5, making a loss of 90 candles in the sum total. But if the current be doubled, each lamp will give a light of 100 candles and the sum total will be 200 candles instead of 10. Having brought a candle or a system of candles up to the point of feeble incandescence, a (proportionally) small addition to the current will make them all brilliant. If at 6,000° Fah., a given carbon will produce a light of 3 candles, at 12.000° it will give 9 candles, and at 24,000° it will give 81 candles; the illuminating power increasing with vastly greater rapidity than the temperature.

The wires supplying the current may be run through existing gas pipes, each lamp being provided with a switch placed conveniently in the wall; and by simply turning a key the light is turned up or down, off or on. So long as the house is connected with the main it makes no difference to the producer whether all the lights are on or off, since the resistance of the entire (house) circuit must be overcome; though it will to the consumer, since a meter records the time that each lamp is on, and the charge is rated accordingly. If the Dynamo-Electric Light Company can supply the illuminating force so cheaply that the constant and brilliant illumination of all the rooms of a house can be secured at no greater cost than the partial and intermittent illumination now had from gas, it is obvious that the electric light will score an important point. The cost of lamps and switches, it is claimed, will not exceed that of gas fixtures.

The meter above referred to is shown in Fig. 6. It is a simple clock arrangement, with an attachment designed to throw
3939 the dial hands into connection when a light is on. From each switch a pair of conducting wires are run to opposite studs on the wooden disk shown at the top of the figure. When no current passes through the lamp the revolving spring shown in front of the studded disk turns without making any record. When the current is on, one electric connection at each revolution is made through the pins assigned to the particular lamp, the armature of the magnet is moved, and the recording wheel is advanced one notch. This meter does not measure the quantity of electricity passing, but only the time a lamp is on. If two or any larger number of lamps are on, an equal number of connections are made at each revolution of the wheel, and the record wheel is advanced to correspond. This registration is, of course, a mere matter of business detail. In view of the well-founded popular dislike to gas meters, however, it would seem to be desirable to dispense with such devices entirely; and the nature of electric distribution appears to favor other and less objectionable modes and means of determining the financial relations of producers and consumers.

Figs. 7 and 8 indicate the method proposed for general distribution. Where the main is tapped for a subcircuit, a shunt is introduced so as to throw so much of the current as may be needed into the derived circuit. The resistance of say 100 added lamps will be about 100 ohms. By giving to the shunt a resistance of one ohm, 1–100 of the current will be diverted, and the lamps supplied. When a large number of lamps are required in a circuit, a combination of the two plans indicated is employed.

The diversion of any portion of the electric supply into an added circuit, whether one house or a group of houses, necessarily increases the aggregate resistance of the electric district, and calls for more work from the generator. To meet such contingencies automatically, Messrs. Sawyer and Man have invented and patented a regulator, which responds instantly to any increase or diminution in the demand, thereby securing an absolutely uniform volume of current.

(Here follow diagrams marked pp. 3940, 3941, 3942, & 3943.)

3944 This regulator so controls the steam or other power actuating the generator of electricity, that the amount of power supplied is increased or diminished in exact proportion to the demand, either by changing the volume of steam produced, or by coupling on or detaching different generators or parts of a single generator in circuit.

With regard to the cost of this mode of electric lighting no positive figures can be given. It is claimed to be entirely demonstrated that one norse power will give by the Sawyer-Man system of incandescence a light of 30 five-foot gas burners an hour. Where large powers are employed the cost of steam power, every item included,

is commonly rated at one cent per horse power per hour. The cost of 150 feet of gas at New York rates is 41 cents, which would make the gas over forty-fold dearer than the Sawyer-Man light. Mr. Sawyer does not stand on this estimate, however, holding that even if the electric light should prove in practice on a large scale to be ten times as costly as calculation indicates, it will yet easily compete with gas, the light furnished being so much better and purer.

It is promised that facilities will soon be offered for the photometric test of a large number of lights, in a circuit, with dynamometric tests of the power employed in generating the electric supply. This, as already noted, is all that the system lacks to prove itself an accomplished economical fact.

3945 Defendant's Exhibit Times Article of Oct. 30, 1878.

A New Electric Light.

The Electro-Dynamic Light Company ready to commence operations.

An interesting exhibition of a new electric light was given by the Electro-Dynamic Light Company yesterday afternoon, at the corner of Elm and Walker streets. The new light is the invention of W. E. Sawyer, of this city, and Albon Man, of Brooklyn. It is a very simple affair, consisting of a small pencil of carbon, a little larger than an ordinary pin, connected by wires with an electric machine, and enclosed in a hermetically sealed glass globe which is filled with pure nitrogen gas. The pencil of carbon is heated by the electric current to a temperature of from 30,000° to 50,000° Fahrenheit in an atmosphere with which it cannot chemically combine. The carbon is practically indestructible and the light is therefore produced without any consumption of material. In the experiments made yesterday five lights were placed in different parts of the darkened room and all connected by wires with a small Hochhausen electric machine in an adjoining room. A simple key was placed in one of three ordinary keyholes in one of the walls and turned a little. Two of the burners attached to a hanging chandelier in the centre of the room immediately glowed faintly and as the key was turned still further around, the glow increased, until a brilliant and perfectly steady white light was obtained equal to the light of 12 ordinary gas jets. The key was then turned in another of the keyholes and another of the lamps was "lighted up." In the same way the fourth and fifth burners were ignited and there resulted an exceedingly brilliant white light, yet so soft and steady that it did not pain the eyes. The lights were easily turned to any desired degree of brilliancy from that of a mere spark to a light of six times the intensity of the common gas jet—that being the
3946 maximum power of the lights in use yesterday. The company asserts its ability to easily fit up lights equal to 30 gas-burners. By a very simple "switch" in the wall the current of electricity is divided and subdivided to supply any number of burners

desired, the electricity reaching the switch from the generator through a single wire. The light is turned on or off, or regulated to any degree merely by turning a key which operates the switch. Messrs. Sawyer and Man have recently taken out a number of patents covering all the points of their new invention which are now the property of a stock company which has been formed to introduce the light to the public.

The plan is similar to that proposed by Edison—the establishing of central stations in various parts of the city from which powerful electric generators will supply the necessary electricity. The company claims to be able to supply the electric light at one-fortieth the cost of ordinary gas. Whether this will prove true or not remains to be seen. The difficulty of a meter has been overcome by the invention of a meter which will record the number of burners used in any given house, and the number of hours each burner is lighted. The measurement of the electricity used would involve so complicated and delicate instruments that the time plan has been adopted. Mr. Sawyer asserted yesterday that Mr. Edison was behind time with his much trumpeted light, as the Electro-Dynamic Company have their light nearly ready for the public and every necessary point is covered by patents of recent date."

THE CONSOLIDATED ELECTRIC LIGHT CO.
vs.
THE MCKEESPORT LIGHT CO.
In Equity.

I, William T. Farnham, special examiner, herein duly appointed, do hereby certify that the foregoing are the proofs for final hearing taken before me in behalf of defendants under the 67th rule of the U. S. Supreme Court in equity as amended under the orders for that purpose herein duly entered.

I further certify that on the dates in said record set forth, the witnesses named therein, to wit, John M. D. Keating, William Hochhausen, William Sharp, Walter K. Griffin, Thomas A. Edison, Cyrus F. Brackett, George F. Barker, William P. Wilson, Amos Broadnax, Henry E. Vineing, Charles Batchelor, William Holzer, Grosvenor P. Lowrey, Calvin Goddard, Robert M. Gallaway, James Hood Wright, Richard N. Dyer and John C. Tomlinson appeared before me and having been by me first duly sworn, they gave their depositions, which were reduced to writing partly by myself and partly by stenographers and typewriters, by consent of counsel for the respective parties, and that said witnesses thereupon signed their several depositions.

I further certify that I am not of counsel or attorney for either of the parties nor in anywise interested in the event of said cause.

I further certify that R. N. Dyer, Grosvenor P. Lowrey, Walter K. Griffin and H. D. Donnelly, Esquires, appeared on behalf of de-

3948 fendants and Thomas B. Kerr, Amos Broadnax, Samuel A. Duncan and Leonard E. Curtis, Esquires, appeared on behalf of complainants at the times and places stated in said record.

Dated New York, May 17th, 1889.

vs.
MCKEESPORT CO.

Edison's Electric Light.

By Francis R. Upton (Mr. Edison's mathematician).

Editor Scribner's Monthly.

DEAR SIR: I have read the paper by Mr. Francis Upton, and it is the first correct and authoritative account of my invention of the electric light.

Yours truly, THOMAS A. EDISON.

Menlo Park, N. J.

The crowning discovery of Mr. Edison—the electric light for domestic use—is at last a scientific and practical success. A mistaken idea has been afloat that this new light was intended to be a rival of the sun, rather than what it really is,—a rival of gas. The contrivances of the new lamp are so absurdly simple as to seem almost an anticlimax to the laborious process of investigation by which they were reached. A small glass globe from which the air has been exhausted, two platinum wires, a bit of charred paper—and we have the lamp. The generator of the electricity is simpler than a gas-generator, and the wires for its distribution are more manageable than are gas mains and pipes. The light is equal to gas in brightness and whiter in color; it is inclosed and, consequently, perfectly steady; it gives off no appreciable heat; it consumes no oxygen; it yields up no noxious gases, and, finally, it costs less than gas. The difficulty of subdivision Mr. Edison has also overcome; in his method of illumination a number of separate lights can now be supplied from the same wire, and each one, being independent, can be lighted or extinguished without affecting those near it.

In order to a clear comprehension of the electric light, a few words upon the general subject are necessary. All illuminants are produced by the incandescence or white heat of matter. This matter may either be in a finely divided state—the particles widely separated—as in the flame of candles, lamps and gas jets, or an aggregation of particles, as in the calcium light. Both of these methods

have been used in the various systems of electric lighting. Electricity flowing through a conductor generates a quantity of heat proportioned 1, to the amount passing through, and 2, to the friction, or resistance, of the medium. Ordinarily, the amount is hardly appreciable in a good conductor. When, however, a poor conductor forms part of the electric circuit, a heat is generated that, under certain conditions, rises steadily to whiteness, causing the substance forming the imperfect conductor to become luminous. If the wire of an electric circuit be cut and the two ends, after being touched, are drawn slightly apart, the current leaps the chasm and a spark appears which vaporizes a small portion of the metal, and this forms a sufficient conductor to enable a constant electrical current to flow from end to end of the wire. When the two ends of the severed wire are properly tipped, a continuous and brilliant light may be produced. Carbon is found to be the best material for these tips, and so long as the current flows and the distance between the points is properly regulated, a storm of white-hot carbon particles is carried across the space, giving a brilliant illumination. This is the voltaic arc, a light produced by the incandescence of finely
3950 divided matter. The broken circuit may be completed by the interposition of some solid matter capable of sustaining a white heat without melting. Platinum and carbon were long thought to be the forms of matter which would best answer the purpose.

These methods of utilizing electricity presented so many difficulties that it was thought impossible to use either for domestic purposes. The objections to the voltaic arc were that the carbon did not offer sufficient resistance to the passage of the current, and that it wasted, the light therefore requiring either continual attention, or else some complicated mechanism, both troublesome and expensive, to keep the distance between the carbon points constant. (See Fig. 3.) The objections to platinum lay in its great cost and rarity, and the fact that its point of fusion is too low to ensure its successful use as the source of light. And finally the objection to all known methods was that the conductors necessary to the supply of any lamp then known would have been of such enormous cost and size as to be impracticable for general use.

In order to understand the difficulties of the problem presented to Mr. Edison, and the simple perfection of his lamp, a short summary of the history of the electric light will be necessary. The first method of illuminating by electricity was by the voltaic arc. About twenty years after the discovery of galvanism, or the modes of generating electricity by chemical decomposition, the voltaic arc was discovered by Sir Humphrey Davy. The battery of a single cell was succeeded by those of multiplied power. In 1812, by the use of a battery of 2,000 cells, Davy succeeded in producing an intensely brilliant arc measuring five inches. The experiment was, however, a very costly one, and had apparently no practical outcome; yet the effects produced by it were so brilliant that Professor Dumas, who repeated it in Paris, in 1834, predicted its final success as an illuminant, in spite of the enormous cost—six dollars a minute. For a number of years no improvement was made, the batteries then in existence being incapable of supplying a constant and steady flow of electricity. Daniell's invention in 1836 of a constant battery, used still in telegraphy, and Grove's improvement in 1839, of electrical generators, gave a new impulse to inventors. A constant and powerful current being supplied by these two inventions, the practical use of it was shortly afterward made in Morse's telegraph. In 1845, about the same time, we find that the first mechanisms for regulating the distance between the carbon points were independently invented by Staite and Foucault, who thus in another direction utilized the electrical power supplied by the batteries. Staite's patents show great inventive genius; in one of them there is a well-defined suggestion of the widely known Jablochkoff candles. In this field of research, as in so many others, the earlier investigators possessed a clearness of vision which enabled them to see further and more accurately than those who came after. Staite, before 1850, produced an electric light, which was exhibited in England, and was so favorably received that a company was organized and gas stock suffered a panic. Many other inventions were made, with a vast expenditure of time, ingenuity and patience, which, like those of Staite and Foucault, failed because of their great cost. It is not enough to invent a good light, nor even to perfect its mechanism; the cost of production must be small enough to enable it to compete with all existing methods of illuminating.

Electric lighting had now passed through three stages. It had been a brilliant laboratory experiment, it had been the subject of practical investigation, and it had been advanced to the precarious dignity of occasional use in the theaters and on great festal occasions. At the coronation of Alexander of Russia, the city of Moscow was lighted by numbers of electric lamps suspended in the old bell tower of the Kremlin, a thousand gilded domes glittering in the unearthly radiance, in happy contrast with the quaint arches of the old cathedral close at hand, while the River Moskva was transmuted into a stream of liquid silver.

The year 1860 saw improvements in generators. The force of steam was found to be convertible into electricity. In 1862 Faraday introduced the electric lamp into a British light-house. France and Brazil tried the same experiment, but even this failed to arouse public interest. The invention of the Gramme generator (though an instrument fully anticipating it had been lying for years in the cabinet of an Italian university) at last gave the impetus needed to set the inventors at work. This was soon followed by the Jablochkoff candles, the contrivance by which some streets in Paris are illuminated. So much for the history of illumination by the voltaic arc.

In 1845, to go back to the second method,—that of illuminating
by an incandescent solid,—an American named Starr, backed
3951 by George Peabody, went to England, and took out a patent
for the use of platinum, which had been already employed
in laboratory experiments, although it had never been used for

practical purposes. In the same year Grove speaks of reading by an incandescent platinum spiral.

In 1847, Dr. Draper, of New York, made a number of experiments to test the qualities of highly heated platinum. He used a lever suspended by a straight wire, very much resembling a door latch held by a string. So marked was the illumination from, and the expansion of, the heated wire at the temperature required for the experiment that he wrote: "An ingenious artist would have very little difficulty, by taking advantage of the movement of the lever, in making a self-acting apparatus in which the platinum wire should be maintained at uniform temperature, notwithstanding any change taking place in the voltaic current." This suggestion, though so clear and practical, lay for twenty years unheeded, and would probably have done so much longer, but that Mr. Edison, with no knowledge of it, entirely independently made use of a similar device and proved himself to be the "ingenious artist," in his first electric light invention.

Fig. 1 shows the plan of the apparatus.* The current enters through the curled wire at the left, and flows from one post, P, to the other, P′, through a spiral and out at the right. It is carried to the top of the glass case, G, then through the straight wire, W, to the lever at A, then to the hinge, H, so that it escapes at the right. In passing through the straight piece of platinum wire, W, enclosed in the spiral the heat generated by the current causes the wire to expand. This expansion allows the lever, L, to fall until it touches the point, B. When this is done the electricity takes the short route through the lever and does not pass through the lamp. The wire, W, contracts and the process is repeated.

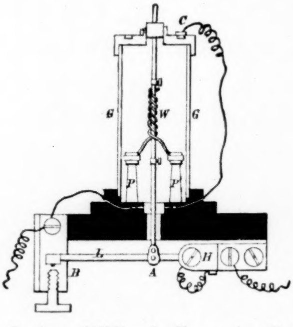

Fig. 1.—*Section of Edison's Expansion Regulator.*

Another method of accomplishing the same purpose is shown in Fig. 2. The current passes, in this case, through the wire, W. In so doing it heats the air in G. The air in expanding forces downward the small metal bellows which is connected with the chamber, until the lever attached below closes the break, B, and short circuits the lamp, allowing the air to cool. These two inventions really belong to the infancy of electric lighting, though invented by Mr. Edison only a short time ago.

---

* The portions marked black in the cuts are insulated.

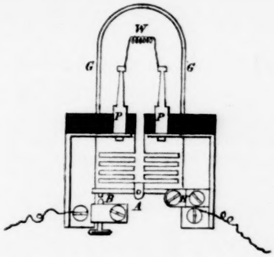

FIG. 2.—*Edison's Pneumatic Regulator.*

In 1849 Despretz describes a series of experiments on sticks of incandescent carbon which were sealed in a glass globe, the air being exhausted, or nitrogen substituted for it. He used several ingenious methods for holding the carbon—patented within the last few years.

So completely had the mode of lighting by an incandescent solid been forgotten, that in 1873 a medal was bestowed by the St. Petersburg Academy on Lodyguine for its supposed discovery, and letters patent were granted to Sawyer and Mann for a stick of carbon rendered incandescent in nitrogen. No successful light by incandescence had, however, been produced when Mr. Edison began his experiments.

In 1878 the lighting of Paris by the Jablochkoff candles was creating a great stir. It had been proved that electricity was really a rival of gas, and that, especially where great concentration was needed, it could take its place. The question now was whether light could be produced in such small amounts as to make it of general domestic use. The money value of an invention which could
compete with gas may be judged from the following items:
3952 The United States has $400,000,000 invested in gas, New
York and the vicinity owning about $35,000,000 of this; England has $500,000,000, $60,000,000 of which is in London. Paris has $40,000,000; Germany $50,000,000, etc. Capitalists, with these figures before them, and the further fact that notwithstanding the great depreciation in plant, the larger portion of this enormous capital was drawing ten per cent., were quick to see an opening for their money and enterprise. Several New York gentlemen, Mr. Grosvenor P. Lowrey and members of the eminent banking-house of Drexel, Morgan & Co. being the most prominent, placed $100,000 in cash at Mr. Edison's disposal, as the requisite means to make the research.

Mr. Edison came to the investigation unhampered by the blunders of his predecessors. He had never seen an electric light. He took hold of the subject in his usual clear-headed, practical way. Next to solving a problem, its intelligent statement is to an investigator the most important thing. Mr. Edison saw that permanence in the lamp and a subdivision of the light were the main things to be sought after. Of the two methods already described, he soon discarded the carbon arc. He perceived that from its nature this arc was inconstant, as its very existence depended upon the destruction of the carbon, and also that it presented greater difficulties in the way of subdivision. Even if he succeeded in conquering the latter

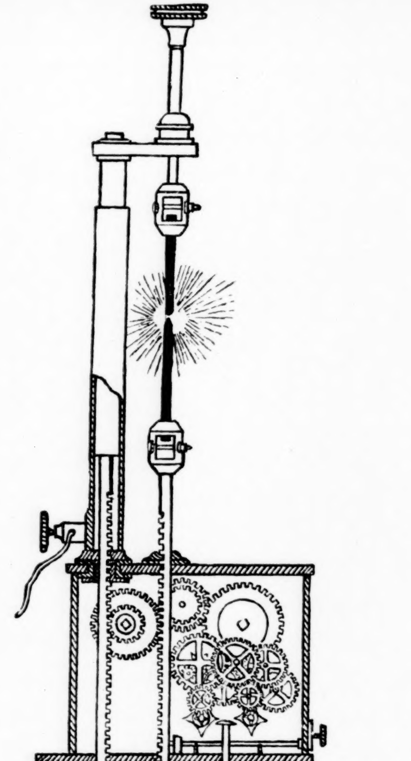

FIG. 3.—*Foucault's Regulator.*

difficulty, and was enabled to produce small lights, the carbon rods waste so rapidly that a system of such lamps would require an expert for every four or five houses to keep it in working order. The most effective apparatus then devised was Foucault's regulator, Fig. 3, which it will be seen is a very complicated piece of mechanism. The Jablochkoff candles, simple as they appear to be, require mechanical contrivances to light them and keep them burning, each candle lasting only a few hours, which makes the constant expense for new burners more than that of the electricity which they can utilize. Mr. Edison, therefore, concentrated his attention wholly upon the light from an incandescent solid.

The advantages of subdivision are twofold and may be explained in a few words. To show that a good gas jet or German student's lamp gives, near the source of light, all the illumination necessary for ordinary domestic purposes, a simple experiment may be tried. A printed page directly under the light, will be seen to be brightly illuminated. After carefully noting this, let another equally strong light be kindled. The room will be brighter, but the page will appear to be scarcely brighter. This is because beyond a certain limit the eye becomes insensible to light. One therefore gains nothing for ordinary use from a single intensely brilliant light. The object of such an illumination being of course to bring, by means of several moderate lights, all parts of the room up to that point where the eye, before it begins to be numb, can utilize the
light. This explains the first advantage of subdivision;
3953 the second is of another kind. Every one familiar with the
electric light, as it has been exhibited, knows that the intense brilliancy of the light and the sharp definition of the shadows as well as their depth, makes it most trying to the eyes. The same amount of light distributed among a number of burners would not give more illumination, but it would be of more practical value, the light would be more diffused, the contrast between light and shadow less sharp and startling. Fig. 4 shows the effect of a shadow from a single brilliant carbon light, and Fig. 5 the effect from sev-

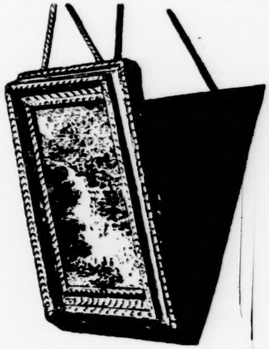

FIG. 4.—*Effect of Carbon Arc Illumination.*

eral shaded lights; the advantage of the latter for practical and domestic use will be readily seen. This is equally true with other illuminators; though gas may be made to give out a brighter illumination per cubic foot when burned in a concentrated form, it is yet more grateful to the eye and less trying when burned as a number of small lights, so that sharp contrast shall be avoided. It is also found that the shape and size of flame, apart from the quantity of light emitted, makes a great difference in this respect—a large light softening the edges of the shadows. The shading of a light, although it obstructs illumination, is useful in diffusing it.

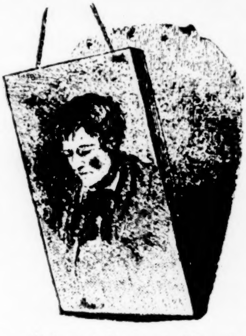

FIG. 5.—*Effect of General Illumination.*

As has been said, Mr. Edison came to the subject unhampered. He saw that subdivision was his goal, and toward that he steadily worked. With a steadfast faith in the fullness of nature, a profound conviction that, if a new substance were demanded for the carrying out of some beneficial project, that substance need only be sought for, he set to work. Two examples of the reward of his faith may be mentioned. One of the great difficulties in the way of illuminating by an incandescent solid—a difficulty constantly urged as insuperable—was that platinum, though the most infusible material which could be drawn out into a wire, still melted at a temperature too low to insure its successful use. Mr. Edison, by experimenting, found that by slowly raising a piece of platinum to a white heat in a vacuum, he could make a practically new metal, the fusing point was so greatly raised. Again, Mr. Preece, chief government electrician in England, declared, and was sustained by many others, that subdivision of the electric light was impossible, because of the enormous size of the conductors and the number of Faradic generators necessary. Edison simply introduced into his lamp an increase of friction or resistance to the electric flow, and the problem was solved.

Mr. Edison's idea in regard to the electric light was that, in all respects, it should take the place of gas. Following the analogy of water, the inventor conceived of a system which should resemble the Holly water works. As the water is pumped directly into pipes which convey it under pressure to the point where it is to be used, so the electricity is to be forced into the wires and delivered under pressure at its destination. In the case of water, after being used, it flows away by means of a sewer pipe, and is lost. But it is easy to imagine that the water used in working machinery, for instance, instead of being lost, might be returned to the pumps and used over and over again. With such a system as this, we should have a perfect analogy to the Edison electric lighting system. The electricity, after being distributed under pressure and used, is returned to the central station. As the light results from no consumption of a material, but is mere transmutation of the energy exerted in the pumping process, it is therefore seen that all which is essential to an electric lighting system is the generator (or pump), 3954 the two lines of wire, one distributing the electricity, the other bringing it back, and a lamp which transmutes into light the energy carried by the electricity when it passes from one wire to the other, and in which the energy of the pressure expresses itself as the light. In Edison's invention the amount of electricity delivered in the lamp is determined by the size and resistance in the carbon, just as in water the amount of flow is determined by the size of the openings. As a great many small jets of water can be supplied from one pipe, so a great many lamps or small escapes for electricity can be furnished from one wire.

As in the case of water, the amount of work done by electricity—either as illuminant or motor—is dependent quite as much upon the pressure from which it escapes as upon the quantity passing through the wires. We might have a system of lamps which would give a certain amount of light from large quantities of electricity escaping under low pressure, or another system which could give an equal amount of light from a small quantity of electricity escaping under high pressure. As in either case the amount of electricity flowing through a wire is in proportion to the size of the wire, it will be readily seen that the application of pressure made by Mr. Edison obviates the main difficulty in the way of subdivision (*i. e.*, in the way of the domestic use of the electric light), namely, the enormous size and cost of conductors. The well-known principle of the effect of pressure upon the dynamic power of electricity had never been utilized because the proper lamp was still unknown. This lamp is Mr. Edison's main discovery. In order to utilize this, one of the plans devised by him was to make the flow of electricity intermittent. Enough was allowed to escape in a short time, say one-third, to keep the lamp all the time supplied. It of course would require a large wire to furnish the quantity of electricity needed, yet two-thirds of the time the wire would be inactive, during which period it could be used to supply two other lamps constructed on the same principle. According to the doctrine of probabilities, one-third of a large number of lamps would be in use all the time. Such being the case, the cost of a conductor would be divided among three lamps. The lamps were so constructed as to burn steadily all the while, although the electricity was passing through them only one-third of the time.

One form of apparatus for accomplishing this distribution among several lamps on the same electrical circuit is shown in Fig. 6. The current conducted by a single wire enters the wire, O, from the lower left-hand corner and flows through the spring, S, by way of B and B; upward through O′, around the magnets, M, M, and out through the lamp, B, B, are two points where the circuit can be broken if the spring, S, is depressed. Two points are made in order that the spark caused by the breaking of the circuit may be made less by division. The spring S is depressed by the arms, C, C, which are attached to the armature, A, by the rod, R. The action is as follows: The current renders the magnet active, it attracts the armature, A, and presses the spring, S, under, stopping the flow of electricity by breaking the circuit at B B. The magnet thus losing its power, the armature is drawn back by the spring to which it is attached and the apparatus is ready to work again. The period of this vibration may be regulated by means of a screw underneath, which can make the excursion of the armature more or less before it breaks the circuit, or can even act to break the circuit itself.

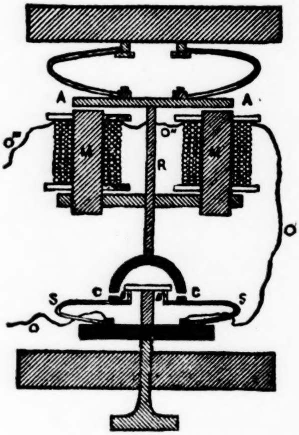

FIG. 6.—*Edison's Vibrating Regulator.*

In making an electric lamp which would be efficient without a regulator (as is Mr. Edison's later invention), two things are essential, great resistance in the wire, and a small radiating surface. Mr. Edison sought to combine these two essential conditions by using a considerable quantity of insulated platinum wire wound like
3955 thread on a spool. This arrangement is shown in Fig. 7.

The spool was made of zircon, pressed extremely hard, and was to be suspended in an exhausted glass bulb by two leading wires. The platinum, as has been incidentally mentioned, was hardened by alternate heating and cooling *in vacuo*, which is done by passing electricity through it till white heat is reached and then cutting it suddenly off. A theory is that the sudden cooling contracts the metal and squeezes out the air contained in it.

FIG. 8.—*Edison's Electric Lamp. Exact size.*

One of Mr. Edison's greatest difficulties was to get a substance with which to insulate his wires that would not melt, and also become a conductor in the intense heat generated by the current,—in which case the electrical flow instead of traversing the whole length of the wire would flow across from layer to layer, or sidewise from wire to wire. This difficulty diverted his attention from platinum to carbon, which is infusible. He did not suspect, at first, that it could be made to offer sufficient resistance to the passage of the electric current, and that through it he was to reach a happy solution of the entire problem. A long time was spent, with a fair degree of success, in seeking to make a spiral of lamp-black tar in the form of a wire. To hold this together he used a bit of ordinary

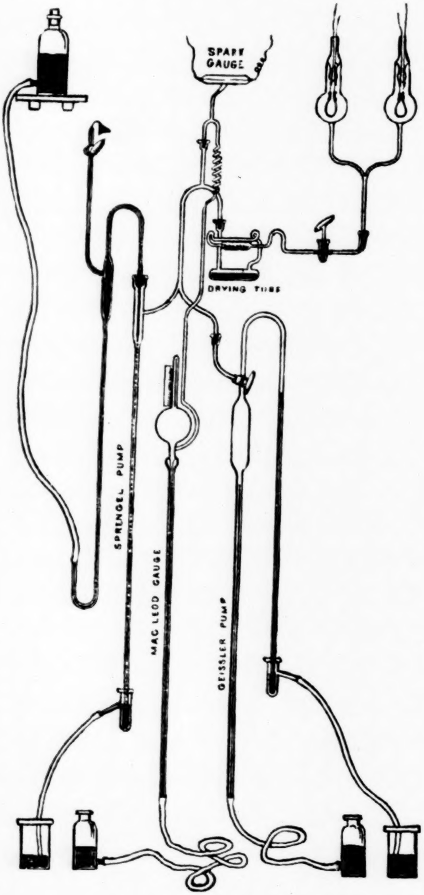

Fig. 9.—*Mercury Pumps for Producing Vacuums.*

sewing cotton which was covered with lamp-black, and succeeded in producing from an inch and a half of this simple thread, bent into an arch, a light equal to an ordinary gas jet. The lamp-black, however, contained air, which greatly interfered with the success of the method. He then used a simple thread, which he found to answer the purpose, though it presented the objection of being fragile, uneven in texture, and unmanageable. This difficulty suggested the use of charred paper, cut into a thread-like form. The difficulties apparently so insuperable melted away. The electric lamp was completed. A piece of charred paper cut into horseshoe shape, 3956 so delicate that it looked like a fine wire, firmly clamped to the two ends of the conducting and discharging wires, so as to form part of the electric circuit, proved to be the long-sought combination. From this a light, equal in power to twelve gas jets, may be obtained. Fig. 8.

The process by which the paper is rendered serviceable is also extremely simple and inexpensive. The horseshoe loops are cut from card-board and placed in layers, within an iron box, with tissue paper between; the box is hermetically sealed, and then raised to a red heat. Nothing remains but the carbon loops and the carbonized tissue paper. All other forms of carbon previously used had presented the difficulty of containing air or gas. The carbonized paper, however, is found to be perfectly homogeneous in structure, elastic, tough, and of an almost vitreous cleavage. It is strong enough to stand far more strain than will be put upon it in any ordinary use. If this paper were burned in air, or in a vacuum prepared by a common air pump, it would of course be almost instantly destroyed. In a high vacuum it burns, but is never consumed. The small glass globe which holds the simple apparatus is exhausted of air by means of nearly the same combination of the Sprengel and Geissler mercury pumps used by Crookes in making his radiometer, or "light mill," and in his wonderful discovery of the phenomena of radiant matter in high vacuums, recently brought before the Royal Society of England. Much attention has been bestowed of late on the question of securing good vacuums. An absolutely perfect one is unattainable. It is, however, found that, by the use of the mercury pumps and chemical appliances, where a nearly perfect vacuum is formed, the minute portion of air remaining shows some remarkable properties. When electricity under strong pressure passes through an Edison lamp, the whole bulb shines with a delicate blue light. So remarkable is the behavior of various substances in a vacuum prepared by means of mercury pumps, that physicists consider that a gas thus rarefied constitutes another state of matter, differing as much from that of an ordinary gas (either under atmospheric pressure or with the pressure removed by means of a common air pump) as a gas differs from a liquid, or a liquid from a solid. Mr. Edison's use of carbon in such a vacuum is entirely new.

The pumps are shown in Fig. 9; the Geissler pump is to the right and below. By raising a bottle which is connected with it, the air is forced out of a large glass bulb, and allowed to escape through

the tube A. On lowering the bottle, the mercury flows back into it, leaving a vacuum in the bulb. The opening of a stop-cock allows some of the air which is left in the pump to flow into this bulb, when the air is again forced out as described; this is continued until the air is exhausted. The working principle of the Sprengel pump is the continuous dropping of mercury through a tube, each drop acting as a piston, carrying before it a small quantity of air. As there is no return stroke, even by the aid of a small tube, the
3957 work of exhaustion goes on quite rapidly. The MacLeod gauge in the center is so constructed that it will measure with exactness when less than one-millionth of the original air is left in the pump.

Another purpose besides that of preventing the destruction of the carbon is served by burning it in a vacuum. Almost all the electricity is converted into light, very little being dissipated by convection or conduction as heat. The little glass globe only an inch from this brilliant light remains cool enough to be handled, and does not scorch tissue paper wrapped closely around it.

Fig. 8 shows the lamp of its actual size. The current enters it by one of the wires, W. At B this copper wire is twisted and soldered to a platinum wire, which passes through the glass at C, and by means of a small platinum clamp into the horseshoe, L, from which, by as simple a route as it entered, it returns. L, the source of light, was made in the form of a horseshoe, in order to approximate to the shape of a gas jet, and is large enough to cause the edges of the shadows to be softened down, and so obviates the common objection to familiar forms of electric lighting. The carbon is sealed in a glass bulb, G G G G, the knob of glass, F, is the melted extremity of the tube by means of which the bulb was connected with the pumps. At the points, C, C, where the platinum wires are sealed into the bulb, some trouble was occasioned by the cracking of the glass, which allowed air to leak into the bulb. It will be noticed that the glass is now drawn up around the wire in a thin tube. This is found to heat and cool so rapidly that it is practically homogeneous with the wire, and even if the wire be heated red hot it will not break. Mr. Edison has tried putting a lamp alternately on and off the circuit for several hours by means of a telegraph key, without loosening the wire. This experiment was equivalent to using the lamp several thousand times.

Mr. Edison has thus succeeded in making a lamp of the simplest imaginable construction, and of materials whose expense is extremely small. The paper costs next to nothing, the glass globes very little, and the platinum tips of the wires are so small that, though the metal used is expensive, their cost is trifling. The test of the value of every invention is its simplicity, and this is the crowning characteristic of Mr. Edison's lamp, for it is really nothing more than a piece of wire looped into a glass globe.

The lamp being complete, let us consider the generator (Fig. 10), for which Mr. Edison has proposed the name Faradic, in honor of the great physicist.

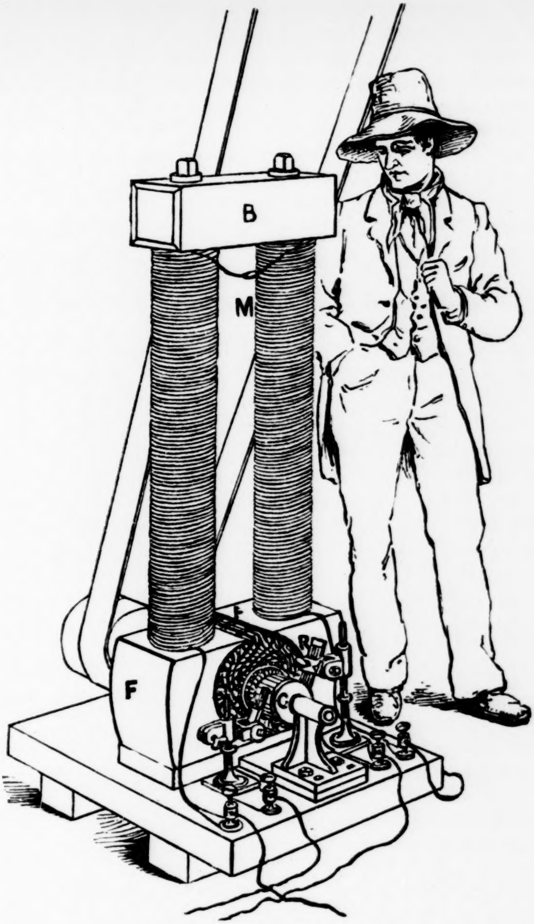

FIG. 10.—*Faradic Generator.*

3958 The cylinder which is placed below, between the blocks of iron, F, on which the magnets, M, rest, is called the armature, and is so arranged that it can be made to revolve rapidly by means of a belt. This armature consists of a small cylinder of wood, which is wound around with iron wire as thread is wound on a spool, the ends being made as in a spool, to hold the wire in place. Around the whole spool are a number of loops of copper wire, covered with cotton thread, running lengthwise of the armature. The ends of these loops may be seen as they are taken from the armature to the cylinder, C, which is an extension of the armature, by which the currents generated in the copper wire may be taken away from the machine. This cylinder, called the commutator, consists of blocks of copper that really represent the ends of the wire, which are placed side by side around the axis of the cylinder in such a manner that no current can pass from one to the other. Touching these as they revolve are brushes, R, made of copper wire, by means of which the electricity flows from the machine.

That the wire about the armature may be able to pump electricity into the line, it is needful that it be revolved immediately in front of magnets. The magnets are made of such large dimensions that the electricity, which is pumped through the machine, may meet with as little friction as possible in passing through the wire of the armature, since by means of the great strength of the magnets, very little wire can be made extremely powerful in forcing the electricity to a higher level or in putting it under pressure. It is exactly as in pumping water, if we have a poor pump (analogous to a machine with a poor magnet) the water may meet with an enormous friction in the pump itself, or require two or more, perhaps, to give it the required pressure, while in a good pump all the parts are so made that while great pressure is given to the water, it passes through it with the utmost freedom. The machine has such strength that it is intended to use only a small fraction of the power, which it could convert into electricity, and deliver outside.

It is proposed to mass a large number of such machines, as in Fig. 11, and have them all pump electricity up from one wire into

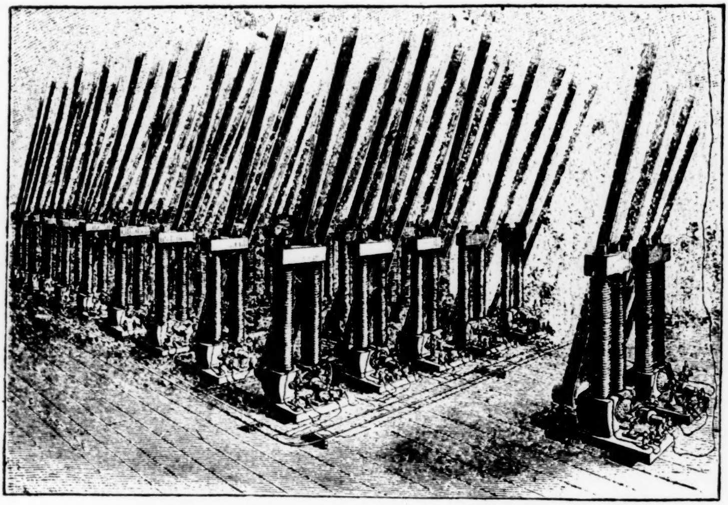

Fig. 11.—*Proposed Central Station.*

a second. The two large wires, held on supports above the floor, are intended, the one to carry the electricity away, and the other bring it back after it has been used. Two machines are placed at one side; these are for the purpose of rendering active the magnets of all the others.

3959 It is proposed to establish such stations in the course of a few months in the heart of several of our large cities. These will supply houses for quite a distance around them. 1,000 horse power is thought to be a sufficient amount for a unit, and the stations will be at such distances from one another that each district will require about this amount. The engines will be divided into four groups of 250 horse power each, with a spare one in each station of the same power.

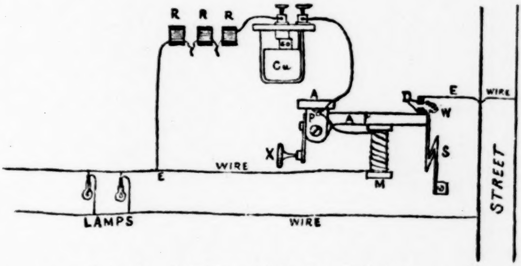

Fig. 12.—*Diagram of Meter and System.*

The wires will be laid in fascines or bundles under the edge of the sidewalk in a tight box. The object of this is to make them easy of access and easy to place in position. Nor is there need of putting them out of the reach of the frost, for they are continuous and not liable to leak from change in position. Even more important is the fact that the colder the wires are the less is the waste of electricity, thus giving a decided advantage over gas in winter, when most light is needed.

The main wires may be either of iron or copper according to the market price of these metals; as quotations are to-day the preference is slightly in favor of copper wire. These lines of wire will start from the central station and send out branches in the same manner that gas or water pipes diverge, growing smaller the farther they are removed from the central station. Fig. 12 also shows the branch wires as they enter the house. It is proposed to color the distributing wires red and the waste wires green. These two distinct wires will be carried all through the house, and every lamp will be so placed that the electricity will flow through it from one wire to the other.

Before passing into the house, the electricity is carried through a sort of meter containing a safety-valve, by means of which it can be measured. The contrivances for doing this are shown in diagram, in Fig. 12, and in perspective in Fig. 13. The lettering is the same in both for identical parts. The current enters at E, passes through the two platinum points, D, then through the armature, A, to the dividing points, P P. The larger portion of the current then flows around the magnet, M. The armature above the magnet is held from it by means of the spring, X. The object of the device is to furnish a means of cutting out a house if too large a flow of electricity by any accident should occur. The magnet would then be capable of drawing down the armature which would separate the platinum points, D, and break the circuit.

The small wire, W, serves a double purpose and is a remarkably clever solution of a double problem. First: If the circuit were partly opened it would weaken the magnet, and the armature would recede, closing the circuit. It would thus form a vibrator resembling Fig. 6. The wire, W, allows enough electricity to pass to close the snap, S, so that the armature is firmly held in place, after which the wire, W, will melt off and completely break the flow of electricity.
3960 Secondly, the wire serves another purpose: If the points were drawn apart an arc would spring between them. The wire, W, conducts the electricity by a shorter route than that offered by an arc and so keeps the space between the two points free from the intensely heated vapors of the metal.

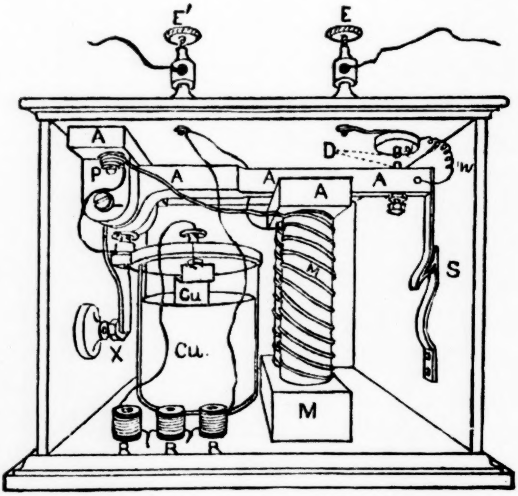

FIG. 13.—*Edison's Electric Light Meter.*

A small fraction of the current passes by another route to the lamps, from the point P. It first traverses a length of wire wound on small spools marked R. The amount placed here will regulate the flow through this line. The current next passes through from one copper plate marked C*u* to another, through a solution of copper salt. In thus flowing, for every unit of current a certain amount of copper is deposited on a thin sheet, the amount for a lamp being once determined by burning one for a number of hours. It must be remembered that only a small amount passes through the meter, but that which passes is proportionate to the whole. It is proposed to make a standard lamp, which shall give a light equal to that from a gas flame consuming five cubic feet each hour. From this it will be calculated how much copper will be deposited, and the amount will be said to represent five cubic feet. The bills for electricity will be made out in 1,000 feet, as in the case of gas. The inspector will take the strip on which the copper is deposited to the central station, in order to determine the amount of electricity used.

Besides giving light, the electricity supplies a convenient form of motor for domestic purposes. A small electrical engine placed beside a sewing machine for example, and connected with the distributing wire, may save all the fatigue of treading the machine, at an expense exactly equal to that of one jet burning for the same time. Elevators may be lifted, lathes turned, and instruments operated up to several horse power, by this same means. Fig. 14 shows the form adopted by Mr. Edison. It is substantially a small model of the large Faradic machine, the only change being in the fact that the armature, C, is placed lengthwise of the magnets, M M, instead of across them. At S is a switch by means of which the motor can be started or stopped. It is expected that the amount of power used in the daytime will largely pay for the expenses of generating—an additional advantage over gas.

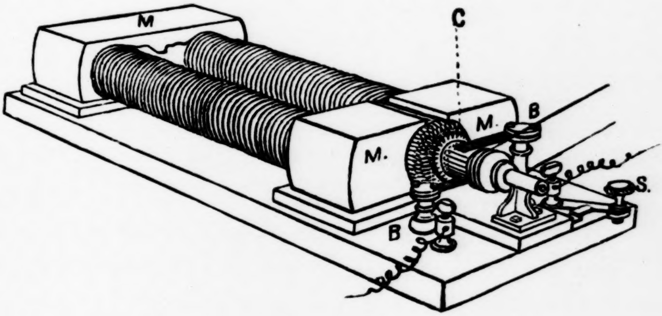

FIG. 14.—*Edison's Electric Motor.*

In order to use the lamp, it is brought into the circuit by turning a handle in a certain direction, or thrown out by reversing the motion, or by means of plugs, which are inserted in a socket. This may be done either in the chandelier or in any other convenient place in the house. Very simple arrangements may be made so that by touching a knob by the bedside the whole house may be brilliantly lighted for the reception or discovery of a suspected burglar. Of course, no matches have to be used; the light kindles itself by the turning of a handle, and so one fruitful source of destructive fires is avoided.

In order that the philosophical relations of the processes may be understood it is needful to trace the history of the energy as it is taken from the coal and conveyed over the wire to the lamp. A large portion of the heat produced by the combustion of the coal under the boiler is found in the steam as it flows to the engine. By means of the latter a small fraction, about ten per cent. of the original energy, is transformed into the motion of the wheels attached to the engine. It may be traced as it flows through the belt to the shaft, and again as it is carried from the shaft to any machine which it may drive. A belt exactly resembles, in carrying power, a man pulling a shaft around by means of a rope. The amount he is pulling can be measured by the strain on the belt, and the work he is doing by determining the speed with which he carries

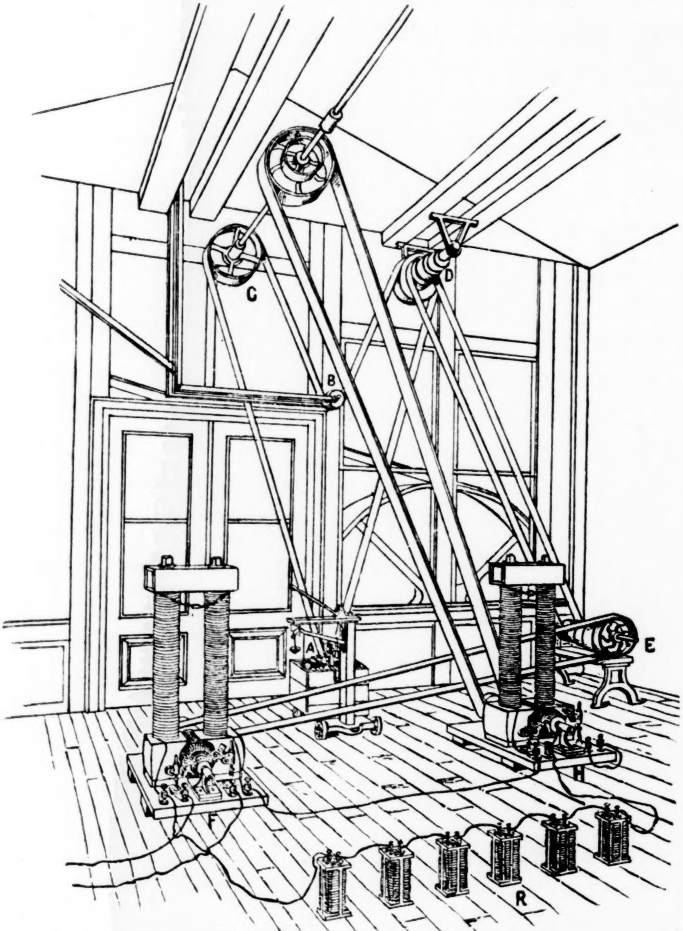

Fig. 15.—*Edison's Dynamometer, for Measuring the Force of an Electric Current.*

the end of the rope. Mr. Edison has made a device, repre-
3961 sented by Fig. 15, to measure this strain. The belt starting
from the pulley over the main shaft, C, is carried under a pulley, A, which is attached to a large box containing heavy weights. This box is placed upon a platform scale. The belt then runs over pulley, D, which it has to drive, and under a wheel, B, which rests heavily upon what would otherwise be the slack part of the belt, for the purpose of tightening it. The pulley, A, attached to the weight, will have a tendency to be drawn upward by any strain that may be put on the belt, just as the block of a tackle is drawn up when the rope is tightened which runs through it. The weight lifted may be measured by the diminution of weight on the scale, one-half of which gives the strain on the belt. Fig. 15 also shows the arrangement of machines as they were placed in order to be tested. The cones D and E were for the purpose of changing the speeds at which the machines were run. The machine, H, at the right, renders active the field of the other machine, F; the current may be regulated by passing through more or less of the resistance boxes, R. By means of this apparatus the exact amount of power carried by the belt can be reckoned when its speed is known. This latter measurement is made from the main shaft.

The energy which the belt carries is seemingly lost, as material motion, when it has turned the armature of the Faradic machine. Since this seems to be a point where the majority lose the track of the energy, in order to explain clearly allusion must be made to some fundamental experiments. Arago many years ago tried this experiment: a sheet of copper, which is not attracted by the magnet under ordinary conditions, was passed between the two poles of a powerful magnet, and it was found to be retarded in its motion. If the magnets are extremely strong, though the copper sheet to the
eye passes through nothing but air, yet to the hand it seems
3962 as if it were cutting cheese, so strong is the drag put upon
the copper. This phenomenon Tyndall calls the apparent viscosity of the magnetic field. Faraday, a few years after this discovery, clearly explained the reason for seeming friction between the plate of copper and the invisible lines of magnetic force which he imagined to reach out from every magnet. He used wires and passed them in front of the magnet, and found that whenever they were made to cut these lines electricity was thrown into the wire. This grand discovery is at the basis of all that is now done in making strong currents, for it furnishes the method by which motion of mass may be transformed into the molecular motion called electricity.

As the energy appears in the wire, it is measured again by an electrical dynamometer, the main idea of which was that of Professor Trowbridge, of Harvard university.

By means of the two instruments, one is enabled to trace out the amount of energy absorbed and given back by the machine, and in many cases ninety per cent. of the original power applied is found converted into electricity. A system of electric lighting is nothing more than a gas system, where energy takes the place of vapors.

It is one of the laws of progress, that no sooner is a method for producing a certain result perfected than a practical use of it follows. This is attested by the history of many great inventions. Following out the laws of discovery, it has been for some time a speculation of the writer that the wonderful perfection to which vacuums had been brought, pointed historically toward some direct connection between them and the electric lamp. For the past few years no more striking result of scientific work has been effected than the startling phenomena shown in high vacuums; parallel with this, a growing want has been felt for a cheaper and more efficient mode of illuminating. Is this a mere coincidence? or may we believe that the demand and means of supply have been developing independently, but side by side; and that now in the electric light we find a practical application of what had been reached by purely theoretical research?

Besides the enormous practical value of the electric light, as domestic illuminant and motor, it furnishes a most striking and beautiful illustration of the convertibility of force. Mr. Edison's system of lighting gives a completed cycle of change. The sunlight poured upon the rank vegetation of the carboniferous forests, was gathered and stored up, and has been waiting through the ages to be converted again into light. The latent force accumulated during the primeval days, and garnered up in the coal beds, is converted, after passing in the steam engine through the phases of chemical, molecular and mechanical force, into electricity, which only waits the touch of the inventor's genius to flash out into a million domestic suns to illuminate a myriad homes.

CHAPITRE III.

Charbons Électriques.

Baguettes en charbon de bois.—Charbon de cornue.—Ses inconvénients.—Charbon Staite et Edwards.—Charbon Le Molt.—Charbon Lacassagne et Thiers.—Charbon Curmer.—Charbon Jacquelain.—Charbon Peyret. — Charbon Archereau. — Expériences de M. Carré.—Ses procédés de fabrication. Expériences de M. Gaudoin.—Ses procédés de fabrication.—Essais comparatifs de diverses sortes de charbons.

Dans ses expériences sur l'arc voltaïque, Davy se servait de baguettes de charbon de bois éteint dans l'eau ou dans le mercure. Ces baguettes brûlaient avec un bel éclat et d'une manière très-régulière, mais elles s'usaient si rapidement, que leur usage était forcément réservé-aux expériences de laboratoire. En remplaçant le charbon de bois par les dépôts recueillis sur les parois des cornues à gaz, Foucault ouvrit réellement à l'arc voltaïque l'ère des applications utiles. Le charbon de cornue est, en effet, beaucoup plus dense et rèsiste bien plus longtemps à l'action destructive du foyer électrique.

Mais, comme l'fait observer avec raison M. Le Roux, le dernier mot n'est pas dit sur cette question, et le charbon de cornue offre encore de graves inconvénients: sa compasité n'est pas uniforme, tant s'en faut; il éclate quelquefois, s'use souvent irrégulièrement et produit des variations d'éclat assez considérables. Ces variations tiennent surtout à la présence de matières étrangères, telles que des sels alcalins ou terreux, et aussi de quantités notables de silice. Ces matières sont beaucoup moins fixes que le charbon, elles
3965 entrent en vapeur et forment pour une grande partie la flamme
qui entoure l'arc. Cette flamme est plus conductrice que l'arc voltaïque proprement dit; en outre, comme elle a une plus grande section, elle s'échauffe moins que lui, et comme, de plus, c'est un corps gazeaux, son pouvoir d'irradiation est moindre que celui des particules charbon-neuses qui constituent l'arc.

Hâtons-nous de dire que, tel qu'il est, en choisissant convenablement les deux baguettes qui doivent garnir un régulateur, le charbon de cornue donne des résultats satisfaisants dans la plupart des applications.

Lorsqu'on renferme l'arc voltaïque dans un globe de verre dépoli, les scintillements, les intermittences et les oscillations dans l'intensité du foyer se font beaucoup moins sentir: les ombres sont moins vives, la lumière est plus douce, plus homogène, plus agréable. Mais le globe est la cause d'une perte de lumière assez considérable et toutes les fois que les petites irrégularités dues à l'imperfection du charbon sont supportables, on laisse brûler les charbons sans globe. On s'habitue d'ailleurs très-facilement à la lumière électrique et les ouvriers, loin de s'en plaindre, recherchent aujourd'hui les usines éclairées par ce procédé.

Plusieurs inventeurs ont cherché à substituer au charbon taillé directement dans les dépôts recueillis sur les parois des cornues, des agglomérés analogues, mais plus purs; d'autres ont simplement purifié les charbons des cornues; quelques-uns ont obtenu des produits très-remarquables au point de vue de l'éclat lumineux, mais irréalisables en pratique à cause de l'exagération du prix de revient.

Parmi tous les procédés proposés et appliqués pour l'amélioration des charbons électriques, nous citerons ceux de MM. Staite et Edwards, Le Molt, Lacassagne et Thiers, Curmer, Jacquelain, Peyret, Archereau, Carré et Gaudoin.

3966

Charbon Staite et Edwards.

En 1846, MM. Staite et Edwards firent breveter un procédé de fabrication de charbon pour lumière électrique qui avait pour base un mélange de coke pulvérisé et de sucre.

Le coke était d'abord réduit en une poudre presque impalpable et additionné d'une petite quantité de sirop, puis le mélange était malaxé, moulé et fortement comprimé. Le charbon subissait ensuite une première cuisson et était plongé dans une dissolution très-concentrée de sucre et soumis de nouveau à la chaleur blanche.

Charbon Le Molt.

M. Le Molt a fait breveter, en 1849, une composition pour crayons électriques, formée de 2 parties de charbon de cornue, 2 parties de charbon de bois ou de coke et 1 partie de goudron liquide. Ces substances étaient préalablement pulvérisées, tamisées, mélangées et amenées par une forte trituration à l'etat de pâte dure très-consistants, puis, à l'aide d'un puissant moyen mécanique, soumises à une forte compression.

Les pièces moulées étaient recouvertes d'un enduit de sirop de sucre et placées les unes contre les autres, dans un vase en charbon de cornue. Elles étaient alors soumises à une haute température pendant 20 à 30 heures et purifiées, si nécessaire, par des immersions dans des acides.

Charbon Lacassagne et Thiers.

MM. Lacassagne et Thiers, en 1857, s'occupèrent de la purification des baguettes de charbons de cornue.

Ces messieurs faisaient fondre, par voie ignée, une cer-
3967 taine quantité de potasse ou de soude caustique. Lorsque
leur bain était à l'état rouge, ils y faisaient digérer, pendant un quart d'heure environ, les baguettes de carbone provenant des parois intérieures des cornues (ces baguettes étaient préalablement taillées).

Cette opération avait pour but de changer en silicate de potasse ou de soude soluble la silice contenue dans lesdits charbons, et si pernicieuse à la constance de la lumière. Les baguettes de charbon étaient en suitelavées à l'eau bouillante, puis soumises (dans un tube de porcelaine ou de terre réfractaire chauffée au rouge), pendant plusieurs heures, à l'action d'un courant de chlore, dont la propriété était de faire passer les différentes terres que la potasse ou la soude n'avaient pas attaquées, à l'état de chlorures volatils, de silicum, de calcium, de potassium, de fer, etc.

Ainsi épurés, ces charbons donnaient une lumière un plus régulière.

Charbon Curmer.

Le procédé Curmer consiste surtout dans la calcination de noir de fumée, de benzine et d'essense de térébenthine, le tout melangé et moulé sous forme de cylindres; la décomposition de ces matières laisse un charbon poreux qu'on imbibe avec des résines ou des matières sucrées et qu'on calcine de nouveau. C'est en répétant ces opérations que M. Curmer réussissait à produire des charbons peu denses et peu conducteurs, il est vrai, mais extrêment réguliers et exempts de toutes impuretés.

Charbon Jacquelain.

M. Jacquelain, ancien chimiste à l'Ecole centrale, a cherché
3968 à imiter les circonstances qui, pendant la fabrication du gaz,
donnent naissance au charbon de cornue. Ces circonstances sont l'arrivée au contact des parois incandescentes des cornues de matières hydrocarburées trés-denses dont une partie se volatilise, et dont le reste se décompose en laissant pour résidu une couche de charbon. Dans les cornues des usines à gaz, ces matières hydrocarburées entraînent avec elles un grand nombre d'impuretés que contient la houille. En prenant des goudrons provenant d'une véritable distillation, débarrassés, par conséquent, de toutes les impuretés non volatiles, et réalisant dans des appareils spéciaux ces conditions de décomposition au contact de parois fortement échauffées, on devait reproduire les charbons des cornues, mais jouissant d'une pureté parfaite. C'est ce qu'a fait M. Jacquelain en opérant avec un tube de terre réfractaire de 0^m, 15 de diamètre dans un fourneau improvisé; et il a obtenu des plaques qui, débitées en baguettes à la scie, ont donné une lumière parfaitement tranquille, plus blanche et d'environ 25 pour 100 plus intense, à courant électrique égal que celle donnée par les charbons ordinaires.

Les expériences faites avec ces crayons, à l'Administration des phares de Paris, avient été si concluantes, que nous eûmes, vers le commencement de 1876, l'idée de mettre le procédé en pratique. Mais M. Jacquelain, consulté, nous expliqua qu'il lui était impossible de calculer: 1e les dépenses à faire pour l'installation d'une fabrication continue; 2e le prix de revient approximatif du charbon obtenu. Comme d'autre part le procédé de M. Gaudoin commençait à donner de bons résultats, nous ne donnâmes pas de suite à notre idée. Nous savons depuis longtemps ce qu'il en coûte pour convertir un procédé de laboratoire, même très-exact, en opération industrielle, et nous ne vouilions pas nous lancer dans une affaire de cette nature sans quelques données numériques.

3969 Les charbons de M. Jacquelain, une fois formés, ont d'ailleurs l'inconvénient d'exiger un travail considérable de main-d'œuvre pour être utilisés (car la matière est si dure, qu'on ne la scie que difficilement) et de produire des déchets relativement considérables.

Charbon Peyret.

M. Peyret, docteur à Lourdes, a préparé des charbons en imbibant des morceaux do moelle de sureau ou tout autre corps poreux avec du sucre fondu et en décomposant ensuite le sucre par la chaleur. En répétant l'operation un nombre de fois suffisant, il obtenait des crayons très-denses qu'il-soumettait ensuite à un courant de sulfure de carbone.

Nous n'avons eu en mains que de très-petits fragments de ces crayons, et il nous a été impossible de nous rendre bien compte de leur valeur; leur prix élevé est en tout cas un obstacle très-sérieux au développement d'une fabrication industrielle.

Charbon Archereau.

M. Archereau, dont le nom revient souvent à la plume lorsqu'on s'occupe de questions d'agglomérés de charbons ou d'électricité, vient de présenter à l'Académie des sciences des nouvelles baguettes pour régulateurs électriques, composées de carbone aggloméré et comprimé, mêlé à de la magnésie, qui ont, d'après l'auteur, l'avantage de rendre la lumière plus stable et d'augmenter son pouvoir éclairant.

Nous avons essayé divers échantillons de ces crayons; les uns étaient de bonne qualité, les autres inférieurs aux charbons de cornue. Plusieurs crayons ont fourni une lumière de 150 becs avec une mesure totale de $0^{m},03$ à l'heure. C'est une fabrication qui peut devenir bonne, mais qu'il faut absolument régulariser.

3970 *Charbon Carré.*

M. Carré a fait un grand nombre d'expériences de lumière électrique sur les charbons de cornue imprégnés de divers sels et a combiné un nouveau produit pour le même usage. Quelques détails sur ses travaux sont nécessaires pour en faire comprendre l'importance et le mérite.

En imprégnant des charbons assez poreux, et par une ébullition prolongée dans des dissolutions concentrées, M. Carre constata :

1° Que la potasse et la soude doublent au moins la longueur de l'arc voltaïque, le rendent muet, se combinent à la silice et l'éliminent des charbons en la faisant fluer à 6 ou 7 millimètres des pointes, à l'état de globules vitreux, limpides et souvent incolores ; qu'elles augmentent la lumiere dans le rapport de 1,25 à 1 ;

2° Que la chaux, la magnésie et la strontiane augmentent la lumière dans la proportion de 1,40 à 1, en la colorant diversement;

3° Que le fer et l'antimoine portent l'augmentation à 1,60 ou 1,70;

4° Que l'acide borique augmente la durée des charbons en les envelloppant d'un enduit vitreux qui les isole de l'oxygène, mais sans augmenter la lumière;

5° Que enfin l'imprégnation des charbons purs et régulièrement poreux avec des dissolutions de divers corps est un moyen commode et économique de produire leurs spectres, mais qu'il est préférable de mélanger les corps simples aux charbons composés.

Pour la fabrication des crayons factices, M. Carré préconise une composition de coke en poudre, de noir de fumée calciné et d'un sirop spécial formé de 30 parties de sucre de canne et de 12 parties de gomme.

3971 La formule suivante est indiquée au brevet du 15 janvier 1876 :

Coke très-pur en poudre fine presque impalpable....	15	parties
Noir de fumée calciné........................	5	—
Sirop spécial..................................	7 à 8	—

Le tout est fortement trituré et additionné de 1 à 3 parties d'eau pour compenser les pertes par évaporation et selon le degre de dureté à donner à la pâte.

Le coke doit être fait avec les meilleurs charbons pulvérisés et purifiés par lavages. (Les poudres charbonneuses peuvent être aussi purifiées par des lavages avec décantation, macération à chaud dans des bains acides.) Le coke des crasses de cornues à gaz est généralement assez pur.

La pâte est alors comprimée et passée par une filière, puis les charbons sont étagés dans des creusets et soumis pendant un temps déterminé à une haute température.

La cuisson comprend uni série d'opérations.

Pour la première, les charbons sont placés horizontalement dans le creuset en fonte sur une couche de poissière de coke, chaque lit est séparé par une feuille de papier pour éviter toute adhérence. Entre la dernière couche et le couvercle, on met 1 centimetre de sable de coke et 1 centimètre de sable siliceux sur le joint du couvercle.

Après la première opération, qui doit durer de quatre à cinq heures au moins et atteindre le rouge-cerise, les charbons doivent rester deux ou trois heures dans un sirop très-concentré et bouillant de sucre de canne ou de caramel, avec deux ou trois intervalles de refroidissement notable, afin que la pression atmosphéric le fasse pénétrer dans tous les pores. On laisse ensuite les charbons égoutter en ouvrant un robinet placé au bas du vase, puis on les agite quelques instants dans l'eau bouillante pour dissoudre le sucre resté à la surface.

3972 Après dessiccation, on soumet les charbons à une seconde cuisson à l'étage qui suit; on peut alors les mettre debout dans le creuset en remplissant leurs interstices avec du sable.

On les traite de même en les descendant d'un étage à chaque cuisson jusqu'à ce qu'ils aient acquis la densité et la solidité requises et en se servant d'un four ayant autant d'étages qu'on désire de cuissons.

Les charbons sont séchés lentement. On termine leur dessiccation dans une étuve dont la température atteint graduellement 80 degrés en douze ou quinze heures. Peur les empêcher de se déformer, en séchant, les baguettes sont placées dans des tôles ayant la forme de V.

Les charbons Carré sont plus tenaces et plus rigides que ceux de cornue. Ils sont surtout remarquablement droits et réguliers. Des baguettes de $0^{m},01$ de diamètre peuvent être employées à $0^{m},50$ de longeuer, sans crainte de rupture. Leur forme cylindrique, jointe à leur homogénéité, fait que leurs cônes se maintiennent aussi parfaitement taillés que s'ils étaient usés au tour. Ils sont aussi plus conducteurs que les charbons de cornue. Les seuls inconvénients que nous ayons remarqués dans l'emploi consistent en une désagrégation assez rapide, la production de petites flammèches et l'irrégularité dans l'éclat lumineux.

Crayons Gaudoin.

M. Gaudoin a également fait de nombreuses expériences sur les charbons contenant des substances étrangères.

Les corps suivants ont été introduits dans les crayons : 1° phosphate de chaux des os ; 2° chlorure de calcium ; 3° borate de chaux ; 4° silicate de chaux ; 5° silice précipitée pure ; 6° magnésie ; 7° borate de magnésie ; 8° phosphate de magnésie ; 9° alumine ; 10° silicate d'alumine.

3973 Les proportions étaient calculées de manière à obtenir 5 pour 100 d'oxyde après la cuisson des crayons. Ceux-ci étaient soumis à l'action d'un courant électrique toujours de même sens, fourni par une machine Gramme assez puissante pour entretenir un arc voltaïque de 10 à 15 millimétres de longueur.

Le crayon négatif étant placé en bas, M. Gaudoin a observé les résultats suivants :

1° La décomposition complète du phosphate de chaux ; sous la triple influence de l'action électrolytique, de l'action calorifique, et de l'action réductrice du carbone. Le calcium réduit se rend sur le charbon négatif et brûle au contact de l'air avec une flamme rougeâtre. La chaux et l'acide phosphorique se répandent dans l'air, en produisant une fumée assez abondante. La lumière, mesurée au photomètre, est double de celle qui est produite par des crayons de même section taillés dans les résidus des cornues à gaz.

2° Le chlorure de calcium, le borate et le silicate de chaux sont également décomposés, mais les acides borique et silicique paraissent échapper par la volatilisation à l'action de l'électricité. Ces corps donnent moins de lumière que le phosphate de chaux.

3° La silice introduite dans les crayons les moins conducteurs diminue la lumière, fond et se volatilise sans être décomposée.

4° La magnésie, le borate et le phosphate de magnésie sont décomposés ; le magnésium en vapeur se rend sur le charbon négatif et brûle au contact de l'air avec une flamme blanche. La magnésie, les acides borique et phosphorique se répandent dans l'air à l'état de fumée. L'augmentation de lumière est moins considérable qu'avec les sels de chaux.

5° L'alumine et le silicate d'alumine ne sont décomposés qu'avec un courant très-fort et un arc voltaïque très-considérable; 3974 mais, dans ces circonstances, la décomposition de l'alumine est bien manifeste, et l'on voit l'aluminium en vapeur sortir du négatif comme un jet de gaz et brûler avec une flamme bleuâtre peu éclairante.

La flamme et la fumée qui accompagnent constamment ces lumières électro-chimiques lui ayant paru un grand obstacle à leur utilisation pour l'éclairage, M. Gaudoin n'a pas poussé plus loin ces expériences. Il a préféré poursuivre ses études sur les agglomérés en carbone.

Les produits fabriqués par M. Gaudoin[1] étant supérieurs à tous les autres, nous allons nous étendre un peu sur leur mode de fabrication.

Le brevet est daté du 12 juillet 1876.

Ainsi que nous l'avons dit plus haut, les crayons destinés à la production de l'arc voltaïque doivent être en carbone chimiquement pur. Or, la poussière de charbon de cornue, quoique ne contenant qu'une faible proportion de matières étrangères, n'est pas suffisamment bonne pour cet usage, et son emploi présente des inconvénients. Les lavages aux acides ou aux alcalis qu'on peut faire subir aux matières charbonneuses, dans le but d'enlever les impurétes qu'elles contiennent, sont coûteux et insuffisants. Le noir de fumée est assez pur, mais son prix est élevé et son maniement difficile. M. Gaudoin a dû chercher ailleurs une meilleure source de carbone, et il a trouvé sa solution en décomposant, par la chaleur en vases clos, les brais secs, gras ou liquides, les goudrons, résines, bitumes, essences et huiles naturelles ou artificielles, matières organiques susceptibles de laisser du carbone suffisamment pur, après leur décomposition par la chaleur.

Les appareils employés pour effectuer cette décomposition 3975 sont des cornues ou creusets fermés en plombagine. Ces creusets sont disposés dans un fourneau capable de les chauffer au rouge clair. La partie inférieure des creusets est munie de deux tubes servant, l'un au dégagement des gaz et matières volatiles, l'autre à l'introduction de la matière première.

On peut conduire les produits volatils de la décomposition sous la grill du foyer et les brûler pour chauffer les creusets, mais il est plus advantageux de les diriger dans une chambre de condensation, puis dans un serpentin en cuivre, et de recueillir, après condensation, les goudrons, huiles, essences et carbures d'hydrogène qui prennent naissance dans cette opération.

M. Gaudoin utilise ces différents sous-produits dans la fabrication même de ses charbons; il a grand soin d'éviter, pour les serpentins et les vases de conservation, l'emploi du fer, de la fonte, du zinc et de toutes substances susceptibles d'être attaquées par ces goudrons, car toute leur valeur réside dans leur pureté.

---

[1] M. Octave Gaudoin est l'inventeur du procédé de galvanisation directe de la fonte et du fer, appliqué en grand au Val d'Osne, lequel donne des résultats bien supérieurs à tous les autres systèmes de cuivrage en usage aujourd'hui.

Quelle que soit la matière première employée à la fabrication de ce charbon, la décomposition par la chaleur peut être menée lentement ou brusquement, selon la nature des produits secondaires qu'on se propose d'obtenir. Pour opérer lentement, il suffit d'emplir la cornue aux deux tiers et de chauffer graduellement jusqu'au rouge clair, en évitant, autant que possible, le boursouflement de la matière. Pour opérer brusquement, on chauffe d'abord la cornue vide au bon rouge, et on fait arriver la matière première au fond par petite portion, soit en filet, si elle est liquide, soit en petits fragments, si elle est solide.

La distillation lente donne plus de goudron et d'huiles lourdes et peu de gaz. La décomposition brusque donne plus d'essences légères et de gaz.

Lorsque la matiére premiére a été convenablement choisie,
3976 il reste dans la cornue du charbon plus ou moins compacte.
On le pulvérise aussi finement que possible et on l'agglomère soit seul, soit mêlé à une certaine quantité de noir de fumée, au moyen des carbures d'hydrogène obtenus comme produits secondaires.

Ainsi préparées ces carbures sont complétement exempts de fer, et sont bien préférables à ceux qu'on trouve dans le commerce, nonseulement par l'agglomération du carbone, mais encore par l'imprégnation ou l'imbibition des objets fabriqués. (Cette dernière opération, tout en bouchant les pores, y introduit de l'oxyde de fer quand elle est faite avec les produits du commerce.)

Les objets faits en carbone agglomere sont, pour une variété de carbone d'autant plus combustibles qu'ils sont plus poreux, et d'autant plus poreux qu'ils ont été moulés à une moindre pression. L'inventeur se sert, pour sa fabrication, de moules en acier capables de résister aux plus hautes pressions d'une forte presse hydraulique.

Quoique la filière, ou appareil à mouler, usitée depuis longtemps dans la fabrication des crayons ordinairs de plombagine, puisse servir sans aucune modification à la fabrication des crayons pour lumière électrique, M. Gaudoin a apporté à cet appareil certains perfectionnements importants. Ainsi, au lieu de faire sortir les crayons de haut en bas, suivant la verticale, il place l'orifice ou les orifices du maule sur le cêté et de manière à ce que les crayons sortent en formant avec l'horizon un angle descendant de 20 à 78 degrés. Les crayons sont guidés sur toute leur longueur par des tubes ou par des rigoles.

Cette disposition permet de vider toute la matière contenue dans le moule sans interompre le travail, et comme les crayons sont constamment soutenus, ils ne cassent plus sous leur propre poids, ce
qui arrive souvent quand ils sortent de haut en bas.
3977 Nous avons fait, à diverses époques, de nombreux essais
avec toutes sortes de crayons, et ce sont ceux de la fabrication de M. Gaudoin qui nous ont donné les meilleurs résultats. Il a

fallu beaucoup de temps et des dépenses d'argent considérables pour faire entrer cette fabrication du domaine scientifique dans celui de la pratique, mais enfin le succès est venu couronner les efforts de l'inventeur.

Tableau des Expériences Faites le 6 *Novembre* 1876 *sur Divers Crayons Électriques.*

Désignation des crayons.	Dimensions.	Vitesse de la machine.	Usure du négatif.	Usure du positif.	Usure totale.	Usure moyenne des deux expériences.	Régularité.	Observations.
			mm	mm	mm	mm		
Cornue	9^{mm^2}	800	19	36	55	63	Irrégulière.	Scintillement, éclipse de courte durée, un peu de désagrégation.
	9	920	23	48	71		Assez régulière.	
Archerau ..	10^{mm} de diamètre.	800	20	60	80	85	Assez régulière.	Un peu de désagrégation, un peu de flammèches.
	10^{mm} de diamètre.	920	30	60	90		Assez régulière.	Cendres d'oxyde de fer en assez grande quantité. Lumière blanche, Taille bonne.
Carré	10^{mm}, 4 de diamètre.	800	18	60	78	92	Irrégulière.	Un peu de désagrégation, un peu de flammèches; plus de cendres que les précédents; rougissant sur une plus grande longueur.
	10^{mm}, 4 de diamètre.	920	26	80	106		Assez régulière.	
Gaudoin ...	11^{mm}, 3 de diamètre.	800	20	38	58	73	Très-régulière.	Pas de désagrégation, ni de flammèches; moins de cendres que les crayons Carré et Archerau.
	11^{mm}, 3 de diamètre.	920	38	50	88		Très-régulière.	

3978 La lumière produite avec les charbons de cornue était égale à 103 becs, et celle produite par les charbons artificiels variait entre 120 et 180 becs pour les crayons Archereau et Carré, et entre 200 à 210 pour les crayons Gaudoin. La moyenne de 150 becs peut être appliquée, sans erreur appréciable, aux crayons Archereau et Carré, et celle de 205 aux crayons Gaudoin.

Ramenée à une section uniforme de 0^{m^2},0001, l'usure des charbons était respectivement :

Pour les charbons de cornue	51	millimètres.
Pour les agglomérés Archereau	66	—
— Gaudoin	73	—
— Carré	77	—

Par rapport à la lumière produite, cette usure était :

Pour les charbons Gaudoin	35	millimètres	pour 100 becs.
— Archereau	44	—	—
— Carré	51	—	—
— de cornue	49	—	—

Ces expériences ont été faites avec une machine Gramme construite par M. Bréguet et une lampe Carré du même constructeur. Les charbons avaient été pris au hasard dans un lot du plusieurs mètres pour chaque catégorie.

Sur la demande d'un des inventeurs, nous avons fait de nouvelles expériences avec le concours de MM. Gramme et Lemonnier, en opérant avec une machine Gramme plus puissante et une lampe Serrin.

Le tableau suivant contient les moyennes de trois séries d'expériences exécutées avec la plus grande précision. La lampe électrique était placée bien verticalement au même niveau que la lampe à huile et que le photomètre. Toutes les précautions étant prises pour qu'il n'y ait aucune erreur sensible dans les mesures d'intensité lumineuse.

3979 *Résultats des Expériences Faites le 4 Avril 1877, sur Divers Charbons.*

Désignation des charbons.	Forme et dimensions.	Section en millimètres Carrés.	Usure totale a l'heure en millimètres.	Lumière moyenne en becs carcel.	Longueur de l'arc en millimètres.	Nombre de tours par minute de la machine.	Régularité.	Observations.
Charbon de cornue, bonne qualité.	Carré. 9^{mm} de côté.	81	60	120	2½	820	Passable.....	Eclats nombreux. Projection d'un petit morceau. Scintillement. Charbons se taillant très-irrégulièrement.
Charbon de M. Archerau. Nouvel échantillon.	Rond. 10^{mm} de diamètre.	78	68	173	3	820	Nulle........	Désagrégation, flammèches, lumière très-variable d'intensité par période. Taille en petites facettes.
Charbon de M. Carré. Nouvel échantillon.	Rond. 9^{mm} de diamètre.	64	69	175	3	820	Médiocre	Petites flammèches. Lumière tournante. Très-variable d'intensité. Bonne taille des charbons.
Charbon de M. Gaudoin. Type nº 1.	Rond. 11^{mm}, 2 de diamètre.	98	80	203	3	820	Bonne.......	Pas de flammèches, ni éclat. Lumière un peu rougeâtre, mais bien constante.
Charbon de M. Gaudoin. (Aggloméré de charbon de bois.)	Rond. 11^{mm}, 5 de diamètre.	78	78	240	3	820	Assez bonne..	Lumière très - blanche. Moins fixe qu'avec les charbons Gaudoin nº 1. Pas de flammèches. Petites variations.

3980 L'usure des charbons, ramenés à une section uniforme de 0^{m2},0001, était respectivement, dans ces nouvelles expériences :

Pour les charbons	Carré	44	millimètres.
—	de cornue	49	—
—	Archereau	53	—
—	Gaudoin (charb. de bois)	61	—
—	Gaudoin n° 1	78	—

Par rapport à la lumière produite cette usure était :

Pour les charbons	Gaudoin (charb. de bois)	32	mill. pour	100 becs.
—	Archereau	39	—	—
—	Carré	40	—	—
—	Gaudoin, n° 1	40	—	—
—	de cornue	50	—	—

La lumière donnée par les charbons Gaudoin n° 1 était un peu moins régulière que celle observée le 6 novembre 1876. Celle donnée par les charbons Carré variait en moins d'une minute de 100 à 250 becs ; elle tournait positivement autour des pointes, comme cela a lieu avec des courants alternatifs. Les crayons Archereau nous ont paru moins bons qu'aux premiers essais ; ils s'usaient lentement, mais ils produisaient des éclats lumineux si variables, qu'il était difficile de prendre des mesures photométriques. Seuls les charbons de cornue avaient conservé leur durée, leur intensité lumineuse, et, malheureusement, leur irrégularité.

Nous signalerons, pour terminer ce chapitre, les perfectionnements que M. Gaudoin vient d'apporter à son procédé et qu'il a fait breveter le 7 avril 1877.

Au lieu de carboniser du bois, de le réduire en poudre et de l'agglomérer ensuite, l'inventeur prend du bois sec, convenablement choisi, auquel il donne la forme du crayon définitif,
3981 puis il le convertit en charbon dur et l'imbibe finalement
comme dans la fabrication que nous avons décrite. La distillation du bois se fait lentement de manière à chasser les corps volatils, et le séchage final est obtenu dans une atmosphère réductrice d'une température très-élevée. Un lavage préalable dans des acides et des alcalis enlève au bois les impuretés qu'il possède.

M. Gaudoin indique également le moyen de boucher les pores du bois en le faisant chauffer au rouge et en le soumettant à l'action du chlorure de carbone et de divers carbures d'hydrogène. Il espère ainsi produire des charbons électriques s'usant peu et donnant une lumière absolument fixe.

Chapitre XI.

Éclairage par Incandescence.

Emploi des tubes de Geissler.—Rapport présenté á l'Académie des sciences par M. Coste, au nom de M. Gervais.—Invention de M. King.—Lampe Lodyguine.—Rapport de M. Wild à l'Académie de Saint-Pétersbourg.—Lampe Konn.—Lampe Bouliguine.—Expériences faites par l'auteur sur l'éclairage par incandescence. Lampe Chérémeteff et Fontaine.

Ainsi que nous l'avons dit, l'arc voltaïque convient éminemment pour l'éclairage des grands espaces à découvert ou des vastes salles sans cloisonnements intérieurs, mais lorsqu'il s'agit d'éclairer de petits emplacements ou de grands locaux très-subdivisés, il est beaucoup plus avantageux d'employer le gaz, le pétrole et même l'huile, ordinaire.

Il a été fait de nombreux travaux sur la creation de petits foyers électriques, mais jusqu'à ce jour aucun des moyens préconisés n'a donné des résultats pratiques. On a notamment cherché à éclairer avec des tubes Geissler et avec des petits charbons incandescents, et, si ces deux moyens n'ont pas réussi, ils offrent néanmoins assez d'intérèt pour que nous leur consacrions quelques pages.

Chacun sait que Geissler, artiste à Bonn, a construit le premier des tubes à ampoules de formes variées, fermés hermétiquement et ne contenant que des traces de vapeurs deverses. Ces tubes, mis en communication avec un courant au moyen de fils de platine scellés dans le verre et d'une bobine Ruhmkorff, produisent une lumière stratifiée, c'est-à-dire composée de couches minces transversales séparées par des couches sombres continuellement agitées.
3983 En même temps les parois des tubes présentent un éclat particulier qu'on désigne sous le nom de fluorescence.

Le 27 mars 1865, M. Coste a présenté à l'Académie des sciences, au nom de M. Gervais, le rapport suivant:

"L'appareil a été construit par M. Ruhmkorff, qui s'est acquitté de ce soin avec son habileté et sa complaisance habituelles. C'est une caisse ou marmite en bronze, montée sur quatre pieds, et son couvercle est hermétiquement appliqué au moyen de vis de pression serrant, entre les deux surfaces ainsi mises au contact, une rondelle annulaire en caoutchouc. Au couvercle est attaché un anneau servant à la suspension de l'appareil optique. La caisse étanche renferme 2 éléments au bichromate de potasse, fermés à leur tour par des plaques que maintiennent des lames de cuivre solidement vissées. Les pôles du courant fourni par les 2 éléments peuvent être, à volonté, mis en communication avec la bobine, et le courant induit, fourni par celle-ci, est porté au dehors à travers la paroi inférieure du récipient, et transmis au tube de Geissler par des fils enveloppés de caoutchouc. Ce tube, d'une forme appropriée et rempli

d'acide carbonique, est enfermé dans un cylindre en verre, à parois épaisses, muni d'armatures en cuivre et dans lequel l'eau ne peut pénétrer. C'est la partie éclairante de l'appareil. On obtient avec cet instrument une lumière douce, mais très-sensible et en tout semblable à celle que le génie militaire et les mineurs emploient maintenant. Elle ressemble sous certains rapport à celle que donnent les animaux phosphorescents, quoique plus intense. Elle peut être aperçue d'assez loin, même lorsque l'appareil fonctionne à plusieurs mètres sous l'eau. Il n'est pas douteux qu'elle ne doive attirer le poisson, comme le fait aussi la phosphorescence de certaines espèces, et l'on pourrait également s'en servir pour éclairer des espaces
3984 restreints, situés au-dessous de la surface de l'eau, ou pour instituer des signaux flottants. M. le capitaine de vaisseau Devoulx, commandant les côtes sud de la France, a vu fonctionner cet appareil dans le port de Cette, au mois de septembre dernier. Il est resté pendant neuf heures immergé, et il a éclairé pendant six heures dans ces conditions, bien que je l'eusse apporté tout chargé de Montpellier. La phosphorescence peut être de plus longue durée. Un second essai, fait à Port-Vendres, à bord du Favori (capitaine Trotabas), m'a également réussi."

La lumière obtenue par les tubes Geissler est tellement faible, qu'on n'a jamais pu l'utiliser pratiquement et que de nombreux essais faits dans les mines et les poudreries sont restés infructueux.

L'éclairage par incandescence a été étudié depuis fort longtemps; mais son application usuelle a rencontré de si grandes difficultés, qu'aujourd'hui on peut encore le considérer comme du domaine purement scientifique, bien qu'il existe déjà un certain nombre d'appareils d'un assez bon fonctionnement.

Le premier document que nous ayons trouvé sur la question est une patente anglaise délivrée le 4 novembre 1845.

M. King, l'inventeur, entre dans des détails précis sur son idée et présente des considérations qui tendraient à prouver que des machines magnéto-électriques, assez puissantes pour produire de la lumière, existaient déjà en 1845.

Voici la traduction des passages principaux de cette patente:

L'invention a pour base l'emploi de conducteurs métalliques ou de charbons continus, chauffés à blanc, par le passage d'un courant électrique. Le meilleur métal pour cet usage est le platine, le meilleur charbon est celui de cornue.

Quand on emploie le charbon, il est utile, à cause de son
3985 affinité pour l'oxygène à haute température, de le mettre à l'abri de l'air et de l'humidité, comme il est indiqué figure 45. Le conducteur C repose sur un bain de mercure; la tige B est en porcelaine, elle sert à soutenir le conducteur C, le conducteur D est fixé sur la cloche par un joint bien hermétique. La baguette en charbon de cornue A repose, en haut et en bas, sur des blocs conducteurs et devient incandescenté par le passage d'un courant électrique. Le vide est préalablement fait dans la cloche, et le mieux est d'employer un véritable baromètre en mettant un des pôles de la pile en communication avec la colonne de mercure et l'autre avec le conducteur D.

Pour obtenir une lumière intermittente, on rompt périodiquement le circuit par un mouvement d'horlogerie.

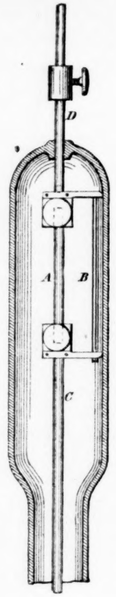

FIG. 45.—*Lampe King.*

3986 L'appareil, convenablement fermé, peut être appliqué à l'éclairage sous-marin ainsi q'à l'illumination des poudreries, des mines, partout où l'on redoute les dangers d'explosion ou l'inflammation rapide de corps très-combustibles.

Lorsque le courant est d'une intensité suffisante, deux ou un plus grand nombre de lumières peuvent être placées dans le même circuit, en ayant soin de régler la puissance des machines magnéto-électriques ou des éléments de la pile, produisant le courant.

En 1846, Greener et Staite se firent breveter pour une lampe analogue à celle de King, en indiquant qu'il serait bon de débarrasser, avant son emploi, le charbon de ses impuretés en le traitant par l'acide nitro-muriatique.

En 1849, Pétrie termine la description d'un brevet de lampe par l'indication suivante : " Une lumière peut être produite en faisant passer un courant électrique à travers un conducteur court et mince qui s'échauffe et devient luminex ; mais la plus grande partie des substances fondent et brûlent rapidement ; cependant j'obtiens une bonne lumière en me servant de l'iridium ou de quelques-uns de ses alliages. L'iridium peut être fondu jusqu' à produire un lingot lorsqu'il est soumis à la chaleur de l'arc voltaïque ; on le décarbonise ensuite et on le rend plus malléable. Puis on le coupe par petits morceaux de 0^m,001 de diamètre et de 0^m,010 à 0^m,020 de longueur que l'on fixe entre deux supports métalliques isolés, lesquels sont en connexion avec les deux fils d'une batterie galvanique convenable. On obtient alors une belle lumière."

Plusieurs autres brevets ont étéé pris en Amerique, en France et en Angleterre dans le même ordre d'idées; mais aucun d'eux ne nous parait plus complet, plus explicite et plus réalisable que celui de King; il est donc inutile de continuer notre nomenclature.

3987 L'éclairage par incandescence et le principe de sa production étaient depuis longtemps tombés dans l'oubli, lorsqu'en 1873, un physicien russe, M. Lodyguine, ressuscita l'un et l'autre et créa une petite lampe, qui fut depuis perfectionnée par MM. Konn et Bouliguine.

En 1874, l'Académie des sciences de Saint-Pétersbourg décerna un grand prix à M. Lodyguine. Voici quelques extraits du rapport présenté à cette occasion par M. Wild, directeur de l'Observatoire impérial russe; ce rapport, comme on le verra, renferme plusieurs erreurs capitales:

"On savait aussi depuis longtemps que l'on peut employer la faculté réchauffante du courant électrique, même sans l'aide d'un gaz comme dans l'arc galvanique lumineux, pour chauffer au blanc un corps solide. Se basant sur ce principe, on a souvent chauffé ainsi des fils de platine minces, donc mauvais conducteurs, en les faisant traverser par un fort courant électrique. La lumière obtenue par ce procédé est beaucoup plus faible et plus constante que la lumière électrique au charbon; elle a aussi plus de force d'extension, et peut être augmentée ou diminuée à volonté; néanmoins, elle n'a jamais trouvé un emploi pratique, parce qu'elle est trop faible en comparaison de son prix de revient, et parce qu'en voulant lui donner plus d'intensité on aboutit facilement à faire fondre le fil de platine, qui, en général, n'est pas tout à fait homogène.

"C'est M. Lodyguine qui, le premier, a eu l'idée de remplacer, dans ces expériences de combustion, le fil de platine par de minces tiges d'un charbon (coke) analogue au graphite, c'est-à-dire bon conducteur, et par là il a résolu le problème de l'éclairage électrique.

"Les avantages de cette substitution du charbon au platine sautent tellement aux yeux aussi au point de vue théorique, que l'on est tout étonné—comme cela est d'ailleurs le cas pour
3988 beaucoup d'importantes inventions—de ce qu'on n'en ait pas
eu l'idée plus tôt. Le charbon posséde, à température égale, un pouvoir beaucoup plus grand de rayonnement que le platine; la capacité calorique du platine est supérieure (presque du double) à celle du charbon en question, bon conducteur, de sorte que la même quantité de calorique élève la température d'une petite tige de ce charbon à un degré presque deux fois plus élevé n'elle ne le fait pour un fil de platine du même volume. En outre, la résistance du charbon en question, comme conducteur d'électricité, est environ 250 fois plus grande que celle du platine; il en résulte que la petite tige de charbon peut être 15 fois plus épaisse qu'une tige de platine de la même longeur et que le courant qui la traverse engendrera la même quantité de chaleur. Enfin, le charbon peut être chauffé au blanc jusqu'au degré le plus extrême sans qu'on ait à en redoubter

la fusion, comme c'est le cas pour le platine. C'est à ces importants avantages théoriques que l'on doit évidemment le grand succès du mode d'èclairage électrique de M. Lodyguine.

"Le seul inconvénient de l'emploi du charbon au lieu du platine consiste en ce que, dans la combustion, le charbon se combine avec l'oxygéne de l'air et se consume ainsi-peu à peu. Mais M. Lodyguine a déjà paré à cet inconvénient en enfermant le charbon chauffé ou blanc par le courant électrique dans un récipient en verre hermétiquement clos et de l'intérieur duquel l'oxygéne est expulsé par un procédé des plus simples.

"Il n'appartient d'ailleurs pas à l'Académie des sciences de donner son jugement ni, d'un côte, sur ces difficultés techniques et d'autres encore qui se présenteront dans l'application en grand de l'invention de M. Lodyguine, ni, d'un autre côté, sur les nombreux avantages pratiques de ce mode d'éclairage comparativement à tous les autres; il suffira à l'Académie d'avoir constaté que, grâce à 3989 cette invention, se trouve résolu, de la manière la plus simple possible, le grand probléme de diviser la lumiére électrique et de la rendre constante[1], pour reconnaître M. Lodyguine, en considération des nombreuses applications utiles de son invention, digne d'obtenia le prix Lomonossow."

Dans sa lampe, M. Lodyguine employait des crayons d'une seule piéce en diminuànt leur section à l'endroit du foyer lumineux, et il plaçait deux charbons dans un même appareil avec un petit commutateur extérieur, pour faire passer le courant dans le deuxième charbon quand le premier était usé. Rien de moins pratique et de moins étudié que les appareils de cet inventeur.

M. Kosloff, de Saint-Pétersbourg, qui vint en France dans l'espoir d'exploiter le brevet Lodyguine, perfectionna un peu sa lampe, sans cependant aboutir à quelque chose de passable.

En 1875, M. Konn, également de Saint-Pétersbourg, fit breveter une lampe plus pratique que nous représentons figure 46, et qui a été construite pour la première fois, en France, par M. Duboscq.

(Here follows diagram marked p. 3990.)

Cette lampe se compose d'un socle A en cuivre sur lequel sont fixées deux bornes X pour attacher les conducteurs, deux tiges C, D en cuivre et une petite soupape K, ne s'ouvrant que de dedans en dehors. Un globe B, évasé à sa partie supérieure, est retenu sur le socle au moyen d'un écrou en bronze L pressant sur une bague en caoutchouc, exactement comme cela a lieu dans les niveau d'eau de chaudiéres à vapeur.

Une des tiges verticales D est isolée électriquement du bàti et communique avec une borne également isolée. L'autre tige 3991 C est formêe de deux parties: 1° d'un tube fixé directement sur le socle sans isolation, et 2° d'une baguette de cuivre, fendue dans une partie de sa longeur. Cette fente lui donne de l'élasticité et lui permet de coulisser dans le tube tout en restant fixe, si l'on n'exerce pas sur elle un certain effort.

---

[1] On verra dans la suite combien le probélme a été peu résolu par M. Lodyguine.

Fig. 46. Lampe Konn.

Les charbons de cornue E, au nombre de 5, sont placés entre les deux petits plateaux qui couronnent les tiges.

Chaque charbon est introduit dans deux petits blocs, également en charbon, lesquels reçoivent des baguettes de cuivre à leurs extrémités. Les baguettes sont égales entre elles à la partie inférieure et de longueurs inégales à la partie supérieure. Une charnère I est articulée sur la tige C et repose sur la baguette d'un seul charbon à la fois.

Si l'on place cette lamp dans un circuit en attachent les deux conducteurs d'une pile aux bornes NN′ (la borne N′ est cachée par la borne N; mais elle est identique et n'est pas isolée du socle), la tige de carbone E est traversée par le courant qui passe par l'intermédiaire de la charnière I, de la baguette de quivre F, des deux blocs de charbon O, O, de la baguette de cuivre G et du plateau couronnant la tige D.

Le vide a été préalablement effectué en plaçant sur l'ajutage de K le conduit d'une pompe à air ou d'une machine pneumatique quelconque.

La tige E rougit, blanchit et devient lumineuse. Sa lumière est d'abord blanche, fixe, constante; puis petit à petit la section diminue, la tige se rompt et la lumière disparaît. La charnière I tombe alors sur une autre tige, et, presque instantanément, l'éclairage est rétabli.

Quand tous les charbons sont usés, la charnière s'arrête sur une tige en cuivre H et le courant n'est pas rompu. De cette manière, s'il y a plusieurs lampes alimentées par un même générateur d'êlectricité, l'extinction de l'une n'entraîne pas celle des autres.

3992 Pour éviter la projection des petits charbons rompus et de leurs blocs contre le verre, M. Konn a placé à la partie inférieure de sa lampe un tube mince en cuivre M, qui reçoit les débris jusqu'à ce qu'on garnisse de nouveau les plateaux.

Trois de ces lampes ont été installées depuis deux ans chez M. Florent, négociant à Saint Pétersbourg, et mises en action avec une machine de l'Alliance. Chaque charbon dure environ deux heures, à l'exception du premier, qui se consume presque immédiatement; la lumière est très-agréable, mais son prix de revient dépasse notablement celui du gaz. M. Florent, que nous avons eu occasion de voir plusieurs fois, nous a dit que le grand avantage qu'il avait trouvé dans l'emploi de l'éclairage électrique était dans sa propreté. Ses magasins renferment beaucoup de linge blanc, que le gaz altérait rapidement et sur lequel l'électricité n'exerce aucune fâcheuse influence. Le blanchissage économisé compense largement les frais supplémentaires nécessités par une installation importante, eu égard au peu de lumière obtenue.

Aucume expérience photométrique n'a été faite chez M. Florent; mais, en comparant avec le gaz, on évalue que chaque lampe Konn donne environ 20 becs Carcel.

La cause principale de la dépense exagérée qu'entraine l'emploi de la lumière par incandescence, réside dans la difficulté de préparer les petits charbons, qui reviennent, en place, à plus de 5 francs le mètre.

Un officier russe, M. Bouliguine, a combiné une lampe (Fig. 47) qui atteint àpeu prés le même but que celle de M. Konn avec un seul charbon. Elle se compose, comme la précédente, d'un socle en cuivre, de deux tiges verticales, de deux barres de prise de courants et d'une soupape d'évacuation.

(Here follows diagram marked p. 3995.)

3993 & 3994 Une des tiges est percée d'un petit trou du haut en bas et possède, sur presque toute sa longueur, une fente permettant le passage de deux petites oreilles latérales.

Le charbon est introduit dans cette tige comme la mine d'un porte-crayon ordinaire, et il est sollicité à monter par dos contre-poids reliés au moyen de deux câbles microscopiques, aux orielles du support en croix sur lequel repose le charbon.

La partie du charbon que doit entrer en incandescence est retenue entre les levres de deux blocs coniques en charbon de cornue.

Une vis, placée sous le socle, permet d'augmenter ou de diminuer la longuer de la tige qui porte le bloc conique supérieur, et, par suite, de donner à la partie lumineuse une plus ou moins grande longuer.

La fermeture du globe est obtenue par la pression latérale de plusieurs rondelles en caoutchouc.

Lorsque la lampe est placée dans un circuit, la baguette de charbon rougit et s'illumine jusqu'à ce qu'elle vienne à se rompre. A ce moment un petit mécanisme[1] commandé par un électro-aimant ouvre les lèvres des porte-charbons, le contre-poid du haut chasse les fragments qui pourraient rester dans l'entaille, les contre-poids du bas relèvent la tige en charbon, laquelle pénètre dans le bloc supérieur et rétablit le courant. Le mécanisme commandé par l'électro-aimant agit de nouveau, mais en sens inverse de sa première manœuvre, les porte-crayons se resserrent et la lumière renaît.

Nous avons, à plusieurs reprises, expérimenté cette lampe et nous
n'avons jamais obtenu de très-bons résultats. Elle renferme
3996 trop d'organes en mouvement, et le moindre obstacle empêche le mécanisme de jouer. Cependant nous avons observé que lorsque par hazard elle fonctionnait régulièrement, les contacts étant meilleurs et moins nombreux que ceux de la lampe Konn, il falliat moins d'intensité de courant pour la production d'un éclat lumineux déterminé. Avec une machine Gramme de 100 becs, nous avons obtenu avec une seule lampe jusqu'à 80 becs, tandis qu'avec une lampe Konn nous ne pouvions jamais dépasser 60 becs.

Pour bien nous rendre compte de la valeur réelle du système d'éclairage par incandescence, nous avons fait faire, sous nos yeux, une série d'expériences avec plusiers lampes Konn et une pile Bunsen de 48 éléments de $0^{m},20$ de hauteur.

La première opération a consisté dans la mesure des résistances du charbon de cornue à section carrée. Les échantillons essayés avaient $0^{m},002$ de côté. Voici les résultats de huit expériences :

---

[1] Le mécanisme en question, que l'exiguïté de notre dessin ne nous a pas permis de figurer, se compose en substance d'une armature en fer placée dans l'intérieur de la lampe et de deux tringles métalliques agissant sur deux leviers croisés et articulés sur la bague enveloppant les porte-charbons.

FIG. 47. Lampe Bouliguine.

Numéros des expériences.	Longueur des échantillons.	Résistance en mètres de fil télégraphique.
1	$0^{m},100$	16^{m}
2	0 ,100	14
3	0 ,100	15
4	0 ,100	14 ,50
5	0 ,100	19
6	0 ,050	7
7	0 ,050	9
8	0 ,050	7
Totaux.......	$0^{m},650$	$101^{m},50$

D'où il résulte que la résistance linéaire moyenne du charbon de cornue de $0^{m},002$ est d'environ 172, celle d'un fil télégraphique de $0^{m},004$ étant prise pour unité.

3997 On a ensuite arrondi les charbons jusqu'à réduire leur diamètre à $0^{m},0016$ et réglé leur longueur de manière à obtenir $0^{m},018$ de partie incandescente. Le vide était obtenu à environ $0^{m},70$ de mercure.

Les résultats ci-dessous représéntent les monennes de plus de 20 séries d'expériences.

État de circuit.	Modes de couplage de la pile.							
	2 séries parallèles de 24 éléments.		3 séries parallèles de 16 éléments.		4 séries parallèles de 12 éléments.		1 seule série de 48 éléments en tension.	
	Indication du galvanomètre.	Intensité lumineuse de chaque lampe.	Indication du galvanomètre.	Intensité lumineuse de chaque lampe.	Indication du galvanomètre.	Intensité lumineuse de chaque lampe.	Indication du galvanomètre.	Intensité lumineuse de chaque lampe.
Circuit fermé sur luimème .	47	"	70	"	70	"	50	"
5 lampes	28	Rouge blanc.	17	Rouge cerise.	10 ou 11	Rouge sombre.	35	½ bec.
4 lampes.......	29	½ bec.	22	Rouge blanc.	16	Rouge orangé.	38	2 becs ½.
3 lampes.......	38	1 à 2 becs.	28	⅓ de bec.	26	¼ de bec.	41	3 becs ½.
2 lampès.......	40	3 becs.	41 à 42	2 becs. ½ à 3 becs.	40 à 45	3 à 5 becs.	44	5 becs.
1 lampe	43	4 à 5 becs.	49	11 à 12 becs.	60	40 becs.	45 à 46	6 becs ½ à 7 becs.

Les lampes étaient groupées comme les éléments d'une pile en tension, elles formaient donc une série unique.

Dans le tableau suivant sont consignés les résultats obtenus avec des lampes assemblées en batteries, c'est-à-dire sur des courants distincts dérivés de la pile. A cause des différences notables reconnues dans les intensités des lumières de chaque lampe, pend-
3998 ant la même expérience, nous donnons la lumière totale au
lieu de celle produite par chaque lampe.

État du circuit.	Modes de couplage de la pile.

1 lampe.........	$52\frac{1}{2}$	9 becs.	$57\frac{1}{2}$	54 becs.	55	63 becs.	46	8 becs.

Plusieurs observations importantes ont été faites pendant les expériences.

Quand les récipients sont étanches et les contacts soiguneusement mis d'aplomb, les charbons ont une durée satisfaisante. Le premier charbon d'une lampe ne dure jamais moins d'un quart d'heure, quelquefois il ne se brise qu'au bout de 30 à 35 minutes, mais cela est très-rare, sa durée moyenne est de 21 minutes. Les charbons qui succèdent, durent en moyenne 2 heures, à moins cependant que l'intensité lumineuse n'atteigne 40 becs, auquel cas ils ne durent en moyenne qu'une demi-heure. Dans l'expérience des 4 séries parallèles de 12 éléments, les 5 lampes étant assemblées en batteries et une seule allumée, le charbon, qui donnait 65 becs, n'a duré que 23 minutes en moyenne.

L'examen attentif des charbons incandescents, à travers
3999 un verre fortement coloré, a montré qu'ils ne sont pas uniformément brillants. Ils présentent des taches obscures, indices de non-homogénété et siéges de gerçures qui désagrégent rapidement le charbon.

Le vide n'étant jamais parfait dans les récipients, le premier charbon est brûlé en grande partie. Il semble qu'ensuite, le peu d'oxygène contenu dans la lampe étante transformé en acede carbonique et oxyde de carbone, le charbon doive se conserver indéfiniment. Mais il se produit alors une sorte d'évaporation qui continue à ruiner lentement les baguettes incandescentes. Cette évaporation est d'ailleurs nettement prouvée par un dépôt pulvérulent de charbon sublimé qu'on trouve sur la surface intérieure des cloches, sur les diverses pièces intérieures : tiges, contacts, charnières, etc.

Aucune cloche n'a été cassée par chaleur ou refroidissement pendant toutes les expériences qui ont duré plusieurs mois, mais plusieures ont eu leur col brise par le serrage trop énergique du joint.

La partie délicate de la lampe est dans la série des contacts qui précèdent la baguette incandescente. On n'obtient l'aplomb des charbons, indispensable à leur durée, qu'avec des précautions minutieuses et longues. Après rupture, le contact ne se reforme pas toujours automatiquement, et une fois sur trois on est obligé de secouer la lampe pour provoquer l'allumage du charbon suivant.

Les rendements maxima ont constamment été ceux obtenus avec une seule lampe et avec 4 étéments de quantité ; dès qu'on employait deux lampes ou qu'on descendait à 2 éléments de quantité, les résultats étaient considérablement diminués.

Nous avons fait tout récemment les mêmes expériences avec des charbons artificiels Gaudoin de même section que les premiers et les résultats ont été plus satisfaisants Ainsi la lumière totale pro-
4000 duite avec 48 éléments en 4 séries et une seule lampe a atteint 80 becs et celle produite avec la même pile et 3 lampes a atteint 30 becs.

La même pile, couplée en tension et agissant sur une lampe Serrin, donnait un arc voltaïque de 105 becs ; mais la lumière obtenue par incandescence était beaucoup plus fixe et plus agréable aux yeux.

De ce qui précède il paraî résulter que le procédé King et Lodyguine est beaucoup plus favorable aux grands foyers qu'à la divisibilité de la lumière électrique ; cependant il convient de remarquer que lorsqu'on ne dépasse pas 10 becs par lampe, les charbons ont une assez longue durée, tandis qu'ils s'usent très-vite pour une intensité de 60 et 80 becs.

Les charbons de $0^m,0016$ de diamètre et $0^m,018$ de longeur lumineuse étaient jusqu'alors les seuls que nous ayons essayés ; ils se comportaient assez bien avec un fort courant, mais ne donnaient aucune lumière avec 12 éléments. Il était intéressant de chercher quelle lumière on peut obtenir avec 12 éléments en diminuant la longueur des charbons. Ce fut le but d'une nouvelle série d'expériences.

Cinq combinaisons diverses one été tentées, en faisant varier tour à tour le couplage de la pile, le diamètre du charbon et sa longueur.

Les meilleurs résultats ont été obtenus avec une lampe unique garnie de charbons Gaudoin de $0^m,0016$ de diamètre et de $0^m,015$ de partie incandescente.

La lumière constatée a varié entre 2 et 8 becs, elle a été le plus souvent de 5 becs. Chaque charbon a duré 15 minutes en moyenne.

Nous devions reprendre toutes ces expériences, en substituent à la pile une machine Gramme combinée pour donner le meilleur

4002 effet utile possible; mais les imperfections des lampes la difficulté d'obtenir de bons contacts, les soins trop minutieux à prendre au commencement de chaque opération, nous ont décide à étudier préalablement une lampe un peu plus commode et un peu plus pratique que celle de M. Konn.

(Here follows diagram marked p. 4001.)

Cette lampe, que nous représentons figure 48, est actuellement en construction chez M. Bréguet. Elle est caractérisée par les deux points suivants: 1° les charbons sont encastrés par chacune de leurs extrémités dans des contacts rigides et maintenus fixes, ce qui permet de faire fonctionner la lampe dans toutes les positions; 2° le courant électrique passe automatiquement d'un charbon à l'autre par l'action d'un électro-aimant intercalé dans le circuit.

Une description, même sommaire, n'aurait pas un grand intérêt, puisque la lampe n'est pas encore exécutée; le desin indique d'ailleurs suffisamment le dispositif que nous avons adopté pour réaliser notre projet.

Lecture Upon the Electric Light.

Delivered Oct. 17, 1878, before the American Gas Light Association,

By Prof. Henry Morton, Ph. D.,

Pres. Stevens Inst., Hoboken, N. J.

(Concluded from page 54.)

In addition to the other forms or modifications of magneto-electric machines—by which name I intend to designate all that I have already described, as I do not think that the term dynamo-electric machines, to designate those in which electro-magnets, excited by the machine itself, are used as producers of the "field of force" or magnetic field in which the revolving magnets move, as distinguished from the earlier sort, using permanent magnets or the like, is at all necessary—there are some others which should not be passed over without notice.

In the first place, Mr. Edward Weston, of Newark, is manufacturing a machine resembling exactly in appearance, and, as far as I can see, in all essentials of construction, that which I have already described and shown as Siemens' later form (see Fig. 27). With several of these machines I have made numerous trials lately, and ~~find them~~ to run well for as much as ten hours at a time, and to give a higher efficiency in light per horse power than any of the other machines with which I have experimented. This re-
4024 sult seems to agree with the general result of experiments made in Europe with the machines of Siemens, and with a

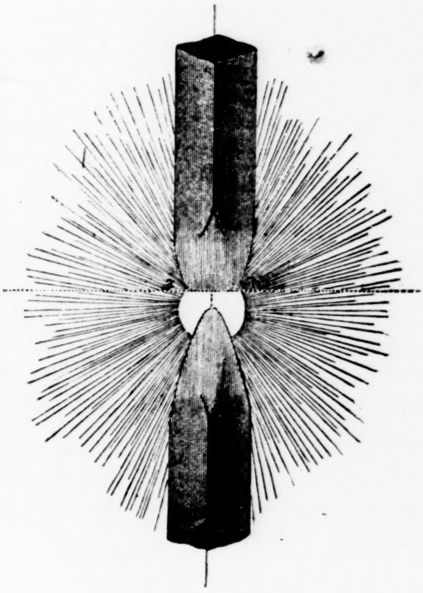

FIG. 40.

general verbal statement which was made to me as to the result of experiments at the U. S. torpedo station at Newport, R. I., where they have one of these Siemens machines.

There is also a very efficient machine manufactured by Messrs. Arnoux & Hochhausen, of New York. Some of these were used very successfully last summer for lighting the bathing beach at Coney Island and for lighting several points in New York during the holiday season this winter and the new state-house at Albany during its inauguration.

One of these was kindly loaned to me on the evening of the address here reported, but as it was soon afterward required for use by its manufacturers I have not had an opportunity to make any examination of or experiments with it. It much resembles the second form of Wilde, or the Farmer machine in general arrangement.

4025 In describing the various forms and modifications of these machines I have not attempted in all cases to follow the chronological order of each step, as this would sometimes have involved the skipping about from one type of machine to another. I will now, therefore, give an abstract of the chronology of the subject, following Dr. Schellen's book as an authority for a part of the list:

1831. Faraday discovered magneto-electric induction.
1832. Pixii made first magneto-electric machine
1833. Saxton made magneto-electric machine.
1836. Clarke made magneto-electric machine.
1849. Nollet-Van Malderen—Alliance machine.
1852. Holmes introduced electro-magnets.
1857. Siemens introduced peculiar armature.
1864. Pacinotti, the first continuous current machine.
1866. Wilde made his first form of machine.
1866. Siemens & Halke, same principle as Ladd.
1867. Ladd, self-exciting principle.
1867. Wheatstone developed same principle.
1871. Gramme first described his continuous current machine.
1873. Wilde described his second form.
1875. Siemens describes his machine. (Fig. 27.)
1873. Farmer patented machine like Wilde's second.
1874. Lontin machine, for many circuits.
1878. Gramme's alternating machine.

In considering the practical application of the electric arc as a source of light, it becomes very important to notice with accuracy just what is the chief location of light in the ignited poles, and how this may be affected by various conditions.

Thus, in the first place, if we are using a machine with a current of uniform direction, we will find that the upper or positive pole, as they are generally arranged, soon acquire a cup-shaped form, as shown in Fig. 40, and that the most intensely luminous portion of the carbon is the interior of this positive cup. The edges of this cup will evidently cut off this light from spreading upward for a
very considerable angle, while on the other hand all the
4026 light from this interior luminous area will pass freely down-
ward. From this it will of course follow that very different results would be obtained if, with such machine and arrangement of the carbons, the lights were measured from below, or on a level, or from above.

If the two carbon points are not placed truly in line with each other, then we have such a state of affairs as is shown in Fig. 41.

Here, evidently, while the light from the hollow positive pole would radiate freely in front, it would be largely cut off behind, and escape only with a medium degree of facility at either side; in fact, measurements made with such arrangements show the following figures:

itted, in a horizontal position, when for the various directions, when they are displaced as shown in Fig. 41: in front, 287; latterly, 116; backward, 38.

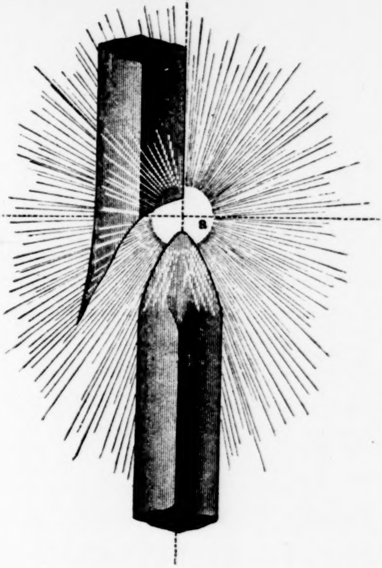

Fig. 41.

4027 In the report of experiments made by a committee of the Franklin institute (see Journal of that society, vol. 75, p. 301) I find the record of a similar set of measurements, as follows:

Front	2,218	candles.
Side	578	"
"	578	"
Back	111	"
	3,485÷4=871	

"The light produced by the machine, under the same conditions, except the carbons being adjusted in one vertical line, was 525 candles. This would seem to indicate that nearly 66 per cent. more light than was produced by this adjustment of the carbons; but a close study of the conditions satisfied us that such is not the case, and there is no advantage to be derived from such adjustment, except when the light is intended to be used in one direction only."

This shows us, among other things, how very great a difference of result in candle power may be obtained with the same apparatus, if a difference occurs in the arrangement of the points; and it also

explains why an arc which giv[illegible]rmer machine in general arrange-
measured, may quite fail to exh[illegible] degree of actual illuminating power when put to some practical use.

Thus, in the case just cited, while the candle power, measured from the front, would be 287, the average for all directions would be only 139, or about one-half as great.

In this connection a certain advantage is found in the use of machines with alternating currents. Here the carbons both burn away alike to the pointed ends, and the light is thus much more equally distributed on all sides. (See Fig. 42.)

In most of the machines now in use the current which produces the light is the same which passes around the coils of the stationary magnets, by which the field of force is developed; hence there is the most intimate relations between the machine and the
4028 lamp, and any fluctuation in the resistance offered at the latter is at once felt at the machine. To eliminate this source of uncertainty and irregularity, in some experiments which I have lately conducted with various machines I have employed a simple, substantial holder for the carbons, with means of adjustment from time to time by hand. This requires, of course, the frequent attention of an assistant during the experiments, but by this means I have obtained more constant and favorable results, from all the machines tried, than with any of the automatic lamps.

Next to this I have found the Brush lamp to be most satisfactory, when used with its own machine.

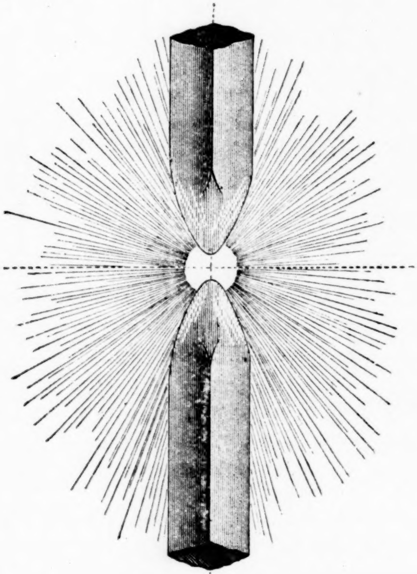

Fig. 42.

As the structure of this lamp is very simple, I will give a description of it here.

This lamp is shown in Figs. 43 and 44, in which *a* is a helix of insulated copper wire, resting upon an insulated plate, *b*, up-
4029 held by the metallic post, *c*. Loosely fitted with the helix
is the core *d*, partly supported by the adjustable springs *e*. The rod, *f*, passes freely through the center of the core, *d*, and has at its lower end a clamp for holding the carbon pencil. A washer, *h*, of brass, surrounds the rod *f*, just below the core. *d*, and has one edge resting on the lifting finger attached to the latter, while the other edge is overhung by the head of an adjustable screw stop, *x*.

The metal post, *c*, is supported and guided by a tubular post, *i*, secured to a suitable base plate. Attached to the lower end of the post, *c*, and passing out through a slot in *i*, is the arm, *y*, supporting an insulated holder for the lower carbon.

If now one conducting wire from the machine be connected to the base plate, and the other to the lower carbon-holder, the current of electricity will pass up through the posts, *i* and *c*, through the helix *a*, rod *f*, and the carbons, *k k*, thus completing the circuit.

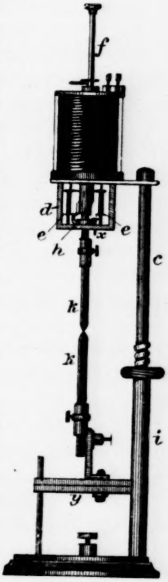

Fig. 43.

The axial magnetism produced in the helix will draw up the core, *d*, and it, by means of the lifting finger, will raise one edge of the washer *h*, which, by its angular impingement against the rod, *f*, clamps and lifts it to a distance controlled by the adjustable stop, *x*, but separating the carbon points far enough to produce the light.

As the carbons burn away, the increased length of the electric arc increases its resistance, and weakens the magnetism of the helix, and therefore the coil, rod, and carbon move downward by the force of gravity, until, by the shortening of the arc, the magnetism of the helix is strengthened, and downward movement arrested. When, however, the downward movement is sufficient to bring the clutch-washer, *h*, to the support, *g*, it will be released from the clamping effect of the lifting finger,
and the rod, *f*, will slip through until ar-
4030 rested by the upward movement of the core,
due to the increased magnetism of the helix.

The normal position of the clamp-washer is with the edge under the adjustable stop, just touching the support, *g*, the office of the core being to regulate the slipping of the rod through it. If, however, the rod, from any cause, falls too far, it will instantly and automatically be raised again, as at first, and the carbon points thus continued at the proper distance from each other.

In the lamps used in these experiments, the helix was composed of two separated insulated wires wound together, so that, by means of suitable pin contracts, shown at the top of Fig. 10, they could be connected either couples or end to end, thus varying the intensity of the magnetism of the helix. Thus, in connection with varying the weight to be lifted by the magnetism of the helix, either by loading the core or increasing the upward thrust of the springs, enabled us to adjust the lamp to suit the varying qualities of the currents dealt with.

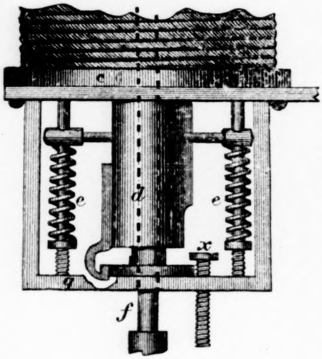

FIG. 14.

Several new methods of arranging the carbons, and rendering them more or less adjustable automatically, have been recently suggested or put in practice.

Thus, in “Nature” for December 19th, 1878, I find a plan
4031 described by Wilde, which consists in placing two carbon
rods beside each other, as in the Jablochkoff candle, but without any insulating material between them. Under these circumstances the author states that the arc will keep to the extremities of the rods, or will run to them if established elsewhere.

To provide against extinction, and secure automatic relighting, one of the holders is hinged so as to allow its carbon to fall against the other unless pulled away by an electro-magnet in circuit. This arrangement is certainly very simple, and free from many of the objections offered in connection with the Jablochkoff candle. It will be seen here, however, that the maximum light will be developed between the two rods, or, in other words, on their respective inner surfaces where it will have the least facility for producing useful effect.

A very curious modification of this candle has been made by Mr. Edward Weston, in which he places a strip of some relatively volatile matter on the backs or outer sides of the parallel carbon rods. The arc then forms across from these parts, and the incandescent vapor assumes much the appearance of a gas flame.

Among the recent forms of lamp described in Dr. Schellen's recent work, “Die Magnet-und Dynamo-Elektrischen Maschinen,” are several announcements by the Siemens-Halske firm.

In one of these two carbons inclined towards each other are allowed to descend, and thus bring their upper ends together by the withdrawal downwards of a non-conducting interposed rod, whose motion is controlled by an electro-magnet in the circuit.

In another, which, however, looks like a suggestion rather than a practicable machine, the carbons are arranged so that the lower one is constantly vibrating up and down, and the upper one simply rests upon it, except in so far as it is being constantly knocked away by the motion of the lower one, which motion is effected by an electro-magnet in the circuit.

A much more complete apparatus, on the same principle we will describe presently.

Among the latest developments in electric lamps may be
4032 reckoned the plan of Mr. Werdermann, which may be described as follows:

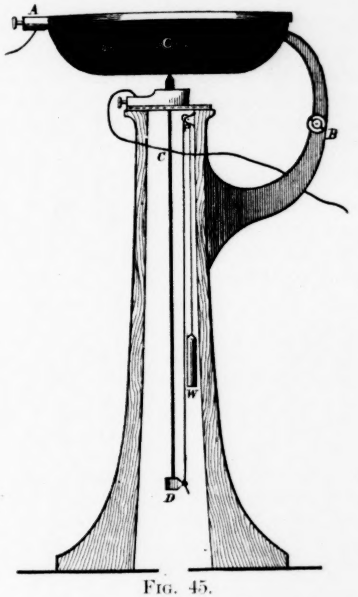

Fig. 45.

Mr. Werdermann makes one electrode to consist of a disc of carbon tapering in thickness from the center to the circumference on one side and flat on the other. The other electrode is a very fine and thin rod of carbon, with one end pointed. The disc is placed horizontally with the rounded side downwards, and the thin rod vertically, and in contact with the disc the current being supplied via the metal collar by which the rod is surrounded near the top. On passing the electricity the fine point of the carbon rod above the collar becomes incandescent, and a very small electric arc is produced between the two carbons. Referring to the diagram (Fig. 45), the upper carbon is shown at C, and the rod carbon at *c*. The former is supported by means of an adjustable jointed bracket
B, attached to the wood stand. The rod carbon is guided by
4033 the spring collar on the top of the stand, and to which the
connection is made, and is supported by the fine cord, run-

ning over the pulley P. This cord is attached to the clasp D at the bottom of the rod and to the balance weight W, by which the rod is maintained in constant, practical, though not absolute contact with the disc. Round the upper part of the disc is a metal band A, to which the circuit wire is attached, and the current thus passed on to the next lamps.

"This lamp" (says the Ironmonger of Nov. 9) "was tried on October 28, and again on November 6, on the works of the British Telegraph Manufactory (Limited), Euston road, London, the current being derived from a small Gramme machine of two-horse power. At the commencement two lights were maintained equal to 640 candles, and the light was perfectly steady. Subsequently the current was sent through a row of 20 lamps the light of each being equal to 40 candles; still the light was steady. Mr. Werdermann asserted his ability to distribute the current from the small machine then at work so as to divide it among 60 lights. In that case the light would inevitably be small; but enough is apparent to prove that, so far as a current will bear division, Mr. Werdermann will be able to utilize it."

It will be noticed that here, as with all other lamps working by incandescence, there is great loss, which increases with the subdivision. A Gramme machine utilizing two-horse power should give, with an ordinary lamp, a light of from 1,000 to 1,500 candles, in place of the 640 here claimed from two lamps, or the 400 candles claimed for ten lamps.

A yet more recent system is that developed or, we might rather say, now in course of development, by Profs. Elihu Thomson and Edward Houston, of Philadelphia, which they have themselves described as follows:

4034 "As is well known, when an electrical current, which flows through a conductor of considerable length, is suddenly broken, a bright flash, called the extra spark, appears at the point of separation. The extra spark will appear, although the current is not sufficient to sustain an arc of any appreciable length at the point of separation.

"In our system, one or both of the electrodes, which may be the ordinary carbon electrodes, are caused to vibrate to and from each other. The electrodes are placed at such a distance apart that in their motion toward each other they touch, and afterward recede a distance apart, which can be regulated. These motions or vibrations are made to follow one another at such a rate that the effect of the light produced is continuous; for, as is well known, when flashes of light follow one another at a rate greater than 25 to 30 per second, the effect produced is that of continuous light. The vibratory motions may be communicated to the electrodes by any suitable device, such, for example, as mechanism operated by a coiled spring, a weight, compressed air, etc.; but it is evident that the current itself furnishes the most direct method of obtaining such motion, as by the use of an automatic vibrator, or an electric engine.

"In practice, instead of vibrating both electrodes, we have found it necessary to give motion to but one, and since the negative electrode may be made of such size as to waste very slowly, motion is imparted to it, in preference to the positive. The carbon electrodes may be replaced by those of various substances of sufficient conducting power. In this system, when desired, an independent battery circuit is employed to control the extinction and lighting of each lamp.

"The following is a description of one of the forms of electric lamp which we have devised, to be used in connection with our system of electric lighting:

"A flexible bar, *b*, of metal is firmly attached at one of its ends to a pillar, *p*, and bears at its other end an iron armature, *a*, placed opposite the adjustable pole piece of the electro-magnet *m*. A metal collar, *c*, supports the negative electrode, the positive electrode being

4035

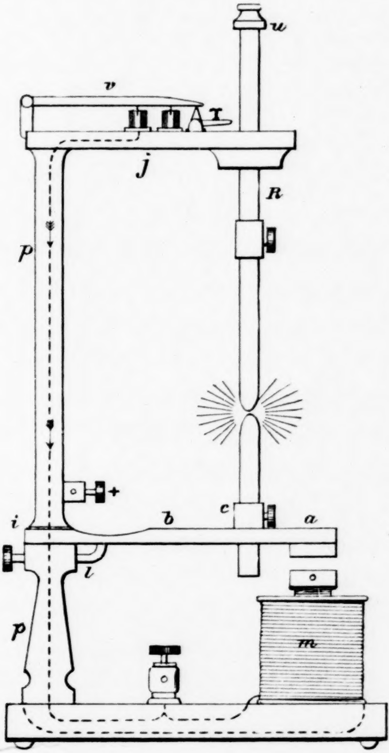

FIG. 46.

supported by an arm, *j*, attached to the pillar, *p*. The pillar, *p*, is divided by insulation at *i* into two sections, the upper one of which conveys the current from the binding post, marked +, to the arm, *j*, and the rod, *r*, supporting the positive electrode.

"The magnet, *m*, is placed as shown by the dotted line the circuit which produces the light. The pillar, *p*, is hollow, and has an insulated conducting wire inclosed, which connects the circuit-closer, *v*, to the binding post, marked —. The current is conveyed to the negative electrode through *b* and the coils of the magnet, *m*. When the electrodes are in contact, the current circulating

4036 through *m* renders it magnetic and attracts the armature, *a*, thus separating the electrodes, when, on the weakening of the current, the elasticity of the rod, *b*, again restores the contact. During the movement of the negative electrode, since it is caused to occur many times per second, the positive electrode, though partially free to fall, cannot follow the rapid motions of the negative electrode, and therefore does not rest in permanent contact with it. The slow fall of the positive electrode may be insured either by properly proportioning its weight, or by partly counterpo-sing it. The positive electrode thus becomes self-feeding.

"The rapidity of movement of the negative carbon may be controlled by means of the rigid bar, *l*, which acts practically, to shorten and lengthen the part vibrating. In order to obtain an excellent but free contact of the arm, *j*, with the positive electrode, the rod, *r*, made of iron or other suitable metal, passes through a cavity filled with mercury, placed in electrical contact with the arm, *j*. Since the mercury does not wet the metal rod, *r*, or the sides of the opening through which it passes, free movement of the rod is allowed without any escape of the mercury. We believe that this feature could be introduced advantageously into other forms of electric lamps.

"In order to prevent a break from occurring in the circuit when the electrodes are consumed, a button, *v*, is attached to the upper extremity of the rod, *R*, at such a distance that when the carbons are consumed as much as is deemed desirable, it comes into contact with a tripping lever, *t*, which then allows two conducting plugs, attached to the bar, *v*, to fall into their respective mercury cups, attached, respectively, to the positive and negative binding posts by a direct wire. This action practically cuts the lamp out of the circuit."

"Philadelphia, Sept. 19, 1878."

In a later publication (Journal of the Franklin Institute for January, 1879), the same inventors describe a further modification and extension of their system as follows:

4037 "The following apparatus was devised by the authors for the purpose of obtaining induced reversed currents for use in electric illumination. These currents we use with a vibrating

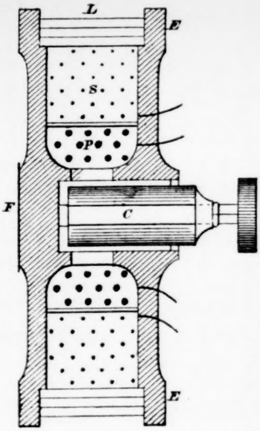

FIG. 47.

lamp, a description of which has already been published.

"Our method of operation is as follows: A reversed primary current is caused to induce reversed secondary currents in secondary coils provided therefor. These secondary currents are caused to give vibrations to carbon electrodes, and thereby at the same time produce a partial arc between them. With sufficient strength of primary current, a considerable number of secondary currents are obtained, each of which is able to operate one of our vibrating lamps.

"The use of a vibrating lamp admits of a wide range in the size of the carbons employed. When a light of very moderate intensity is desired, the carbons are made very small size, and are placed in a closed glass vessel for protection from the atmosphere. To moderate the brilliancy opalescent glass is used. To obtain the highest efficiency of inductive action from a set of primary coils, the following form of induction of coil was devised:—the primary coil, *P*, surrounding the core, *C*, is provided with a secondary coil, *S*, adjacent to it. The ends *E* and *F* of the bobbin are made of disks of iron concentric with the core, *C*, and slit from centre to circumference. The outer extremities of these disks are connected by wires or sheets of iron, *L*, to one another, forming in this manner an induction coil encased in iron, or one whose core has its north and south extremities magnetically connected. The strength of the current developed in the secondary coil is greatest when the core, *C*, which is movable, is inserted so that both of its extremities are in contact with *E* and *F*. By withdrawing this core, the
4038 currents in the secondary coil may be weakened to almost any desired extent. This coil is best adapted to the use of primary currents whose direction is constantly changing. All the wire being completely surrounded by iron, whose direction of magnetic polarization *if* rapidly changed, the highest inductive effect is thereby produced in the secondary coil.

"The variations in the intensity of the induced currents will, of course, be followed by variations in the intensity of the light emitted by the lamp. The movement of the core may therefore be made to increase or decrease the intensity of the light."

With this notice of the newest, or, as we may say, youngest system of electric lighting, which has its birthday with the new year, I may well conclude this hastily prepared and imperfect notice of this very interesting subject, and if what I have here thrown together may supply at least material for a fuller treatment, or a skeleton on which a completely organized structure may be constructed, I shall have accomplished all that I could hope.

Before concluding this address I should draw attention, in a more direct manner, to something which has been developed indirectly in the course of my remarks; and that is that the loss of efficiency in the electric force as a means of producing light, when it is divided, is not a unique phenomenon, but is exactly parallel in the case of ordinary combustion.

If gas is burned in very small flames we may get almost no light from it, and, on the other hand, if we burn it in very large flames, the amount of light developed will increase in a much higher ratio than will the amount of gas consumed.

Thus I have here a new burner made by Sugg, of London, with three concentric argand rings which burns 30 feet of gas, and yields a light equal to 196.4 candles. The same amount of the same gas burned in six standard five-foot burners yielded a light of 114 candles. Here is a gain of over 70 per cent. in the total light produced by simply concentrating the combustion in one large flame in place of dividing it into six small ones.

4039 In the case of the ordiary lime light we have another instance of yet further concentration.

Here, with a consumption of about 7½ feet of gas an hour, in a burner with three jets heating a cylinder of lime from all sides, we obtain a light equal to 260 candles in every direction.

This shows very clearly the illogical character of the comparisons so often made between the concentrated light of the electric arc and the divided light of the ordinary gas-burner.

Heretofore electric lights have only been practically developed in their concentrated form, and it certainly has not yet been shown that, when divided, there will be an enormous loss of efficiency. Gas, on the contrary, has heretofore only been practically used in its divided form, and there can be no doubt that its efficiency is capable of much increase when it is burned in a concentrated manner.

It is here where the actual contest will come in, and the relative success of the two sources of light in each field will depend upon what it will accomplish in that field and not in some other. In other words, we must compare the divided electric lights (say Mr. Edison's, when they become visible) with ordinary burners, and the electric-arc light with the lime light, or some such concentrated form of gas-burning.

THE END.

(See comparative table marked p. 4040.)

CHAPTER III.

Electric Carbons.

Wood carbon rods.—Retort carbon.—Its inconveniences.—Staite and Edward's carbons.—Le Molt's carbons.—Lacassagne and Thiers' carbons.—Curmer's carbons.—Jacquelain's carbons.—Peyret's carbons.—Archereau's carbons.—Carré's experiments.—His processes of manufacture.—Gaudoin's experiments.—His processes of manufacture.—Comparative trials of several kinds of carbons.

In his experiments on the voltaic arc, Davy made use of rods of wood carbon extinguished in water or mercury. These rods burnt with great brilliancy, and in a very regular manner, but they wore away so rapidly that their use was obliged to be reserved for laboratory experiments. In replacing the wood carbon by the deposits collected from the walls of gas retorts, Foucault really opened up to the voltaic arc the epoch of useful applications. Retort carbon is, in fact, much more dense, and resists for a long time the destructive action of the voltaic focus.

But, as M. Le Roux has observed with reason, the last word has not been said upon this question, and retort carbon will still offer grave inconveniences: its density is far from uniform, it sometimes splits, frequently works irregularly, and produces considerable variations in brilliancy. These variations chiefly depend upon the presence of foreign matters, such as alkaline or earthy salts, and also notable quantities of silica. These matters are much less refractory than the carbon; they pass into vapour, and form for a great part the flame which envelopes the arc. This flame is more conducting than the voltaic arc proper; moreover, as it has a much greater section it is less heated, and besides, as it is a gaseous body, its power of radiation is less than that of the particles of carbon which constitute the arc.

Let us hasten to say that, by suitably choosing the two rods which should furnish a regulator, retort carbon gives satisfactory results in most of its applications.

4043 When the voltaic arc is enclosed in a globe of frosted glass, the scintillations, intermittences, and variations in the intensity of the focus are much less felt; the shadows are much less marked, the light is softer, more homogeneous, more agreeable. But the globe causes a very considerable loss of light, and whenever the small irregularities, due to the imperfection of the carbon, are supportable, the carbons should be burned without a globe. Moreover, one gets readily accustomed to the electric light; and workmen now, instead of complaining, seek factories lighted in this manner.

Several inventors have endeavoured to substitute for carbons cut directly from the deposits on the walls of retorts similar agglomerates, but purer; others have merely purified retort carbons. Some have obtained products very remarkable in respect of luminosity, but practically inapplicable on account of their extreme cost.

Among the processes proposed for the improvement of electric carbons, we will cite those of Messrs. Staite and Edwards, Le Molt, Lacassagne and Thiers, Curmer, Jacquelain, Peyret, Archereau, Carré and Gaudoin.

Staite and Edwards' Carbon.

In 1846, Messrs. Staite and Edwards patented a process for the manufacture of carbons for the electric light, which had for its base a mixture of pulverised coke and sugar.

The coke is first reduced to a nearly impalpable powder, and a small quantity of syrup added, the mixture being pugged, moulded, and strongly compressed. Then the carbon is subjected to a first heating, and plunged into a very concentrated solution of sugar, and again subjected to a white heat.

Le Molt's Carbon.

M. Le Molt, in 1849, patented a composition for electric carbons, consisting of 2 parts of retort carbon, 2 parts of wood charcoal or of coke, and 1 part of tar. The substances were in the first place
4044 pulverised, pounded, mixed, and much trituration brought
to the state of a stiff paste; then, by the aid of powerful mechanical means, subjected to great compression.

The moulded pieces were covered with a coating of syrup, and placed beside each other in a vessel of retort carbon. They were then subjected to a high temperature for a period of from twenty to thirty hours, and purified, if necessary, by immersion in acids.

Lacassagne and Thiers' Carbon.

In 1875, Messrs. Lacassagne and Thiers gave attention to the purification of retort carbons. They fused a certain quantity of caustic potash or soda. When this bath was at a red heat they digested in it, for about a quarter of an hour, the carbon rods which had been previously cut from the walls of retorts.

This operation was intended to change into a soluble silicate of potash or soda the silica contained in the carbons which is so pernicious to the constancy of the light. The carbon rods were then washed in boiling water, and subjected for several hours (in a red-hot tube of porcelain or fire-clay) to the action of a current of chlorine, which had the effect of converting the different earthy matters that the alkali had not attacked into volatile chlorides, as of silica, calcium, potassium, iron, &c. Thus cleansed, these carbons gave a somewhat more regular light.

Curmer's Carbon.

Curmer's process consists principally in the calcination of lampblack, benzine, and oil of turpentine, the whole mixed and moulded in the form of cylinders; the decomposition of these substances leaves a porus carbon, which is soaked with resins or saccharine matters and again calcined. By repeating these operations, M. Curmer succeeded in producing carbons of small density or conducting power certainly, but extremely regular, and free from all impurities.

Jacquelain's Carbon.

M. Jacquelain, late chemist at l'École Centrale, has endeavoured to imitate the circumstances which, during the manufacture of gas, give birth to retort carbon. These circumstances are 4045 the coming into contact with the white-hot walls of the retort of very dense hydrocarburetted matters, of which part is volatilised and the rest decomposed, leaving as residue a layer of carbon. In the retorts used in the manufacture of gas, these hydrocarburetted matters carry away with them a great number of the impurities that the coal contains. By taking the tars resulting from true distillation, cleared consequently of all the non-volatile impurities, and realising, in special apparatus, these conditions of decomposition in contact with highly heated walls, retort carbons ought to be reproduced possessing perfect purity. It is this that M. Jacquelain has done in operating with a tube of refractory earth of 0·15 mètre diameter, in an improvised furnace; and he has obtained some plates which, cut into rods with a saw, have given a light perfectly steady, whiter, and of about 25 per cent. greater intensity, with an equal electric current, than that given by the ordinary carbons.

The experiments made with these carbons, by the Paris administration of light-houses, have been so conclusive that we had, about the commencement of 1876, the idea of putting the process in practice. But M. Jacquelain, being consulted, explained to us that it was impossible to calculate: 1st, the expenditure necessary for the establishment of a continuous manufacture; 2nd, the approximate nett cost price of the carbons obtained. As another process by M. Gaudoin has commenced to give good results, we have not continued our idea. We have long ago learnt what is the cost of converting a very exact laboratory process into an industrial operation, and we do not wish to launch into an affair of this nature without some figures being given.

The carbon of M. Jacquelain, once formed, has always the inconvenience of requiring a considerable amount of manual labour before use can be made of it (because the material is so hard, that it can with difficulty be cut by the saw), and of producing relatively considerable waste.

Peyret's Carbon.

M. Peyret, a physicist of Lourdes, has prepared carbons by
soaking pieces of elder-tree pith or any other porous body
4046 with liquefied sugar, and afterwards decomposing the sugar
by heat. By repeating the operation a sufficient number of
times, he obtained very dense carbons, which he then submitted to
a current of sulphide of carbon.

We have had in our hands only very small fragments of these carbons, and it has been impossible for us to give an estimate of their worth; their high price is in every case a very serious obstacle to the development of an industrial manufacture.

Archereau's Carbon.

M. Archereau, whose name frequently comes under the pen in questions relating to agglomerates of carbon or to electricity, has presented to the Academy of Sciences some new rods for electric regulators, composed of carbon mixed with magnesia, agglomerated and pressed; the magnesia has, according to the author, the advantage of making a light more steady and of augmenting its lighting power.

We have tried several samples of these carbons, some were of good quality, others inferior to retort carbons. Several carbons furnished a light of 150 burners, with a total consumption per hour of 0·03 mètre. It is a manufacture that is capable of giving good results, but needs very careful revision.

Carré's Carbon.

M. Carré has made a great number of experiments for the electric light upon retort carbons impregnated with different salts, and has combined a new product for the same usage. Some details of his labors are necessary to make their importance and merit understood.

By impregnating porous carbons, and by a prolonged ebullition in concentrated solutions, M. Carré proves:

1st. That potash and soda at least double the length of the voltaic arc, render it more silent, combine themselves with the silica and eliminate it from the carbons by making it flow to 6 or 7 millimètres from the points in a state of vitreous globules, limpid, and
often colourless; that these substances augment the light in the
proportion of 1·25 to 1;

4047 2nd. That lime, magnesia, and strontia augment the light
in the proportion of 1·40 to 1, by the colouring in different
ways;

3rd. That iron and antimony carry the augmentation to 1·60 or 1·70;

4th. That boracic acid augments the duration of the carbons by enveloping them with a vitreous layer which isolates the oxygen from them, but without augmenting the light;

5th. That upon the whole the impregnation of pure and regularly porous carbons, with the solutions of different substances, is a convenient and economical means of producing their spectra, but that the mixing of the simple substances with the carbon compound is preferable.

For the manufacture of carbons, M. Carré recommends a composition of powdered coke, calcined lamp-black, and a special syrup formed of 30 parts of cane sugar and 12 parts of gum.

The following formula is recommended in the patent of the 15th January, 1876:

Coke, very pure, in fine, nearly impalpable powder..	15 parts
Calcined lamp-black...........................	5 "
Special syrup....................................	7 to 8 "

The whole is strongly triturated, and has added to it from 1 to 3 parts of water, to compensate for the loss by evaporation, according to the degree of toughness to be given to the paste. The coke ought to be made with the best coals, pulverised and purified by washings. (The coal powder may likewise be purified by washings by decantation and maceration with heat in acid baths.) The coke dust of gas retorts is generally pure enough.

The paste is now pressed and passed through a draw-plate, then the carbons are placed in tiers in crucibles, and are subjected during a given time to high temperature.

The cooking comprehends a series of operations.

For the first, the carbons are placed horizontally in the crucible resting upon a bed of coke dust, every layer is separated by a cover of paper to avoid any adherence. Between the last layer and the cover is put one centimètre of coke sand, and one centimètre of silicious sand upon the joint of the cover.

4048 After the first operation, which ought to last from four to five hours and attain a cherry-red heat, the carbons should remain two or three hours in a very concentrated and boiling syrup of cane sugar or caramel, with two or three intervals of considerable cooling, in order that the atmospheric pressure may force the syrup into all the pores. The carbons are then left to drain by opening a cock placed at the bottom of the vessel, after which they are agitated for some instants in boiling water to dissolve the sugar remaining on the surface.

After desiccation the carbons are submitted to a second cooking to the degree required; they are then stood up in the crucible by filling up their interstices with sand.

They are thus manipulated from stage to stage until they have acquired the density and solidity requisite, and the manipulation is facilitated by the use of an oven having as many stages as there are cookings required.

The carbons are dried slowly. Their desiccation is completed in a stove, the temperature of which attains gradually 80 degrees in twelve or fifteen hours. To prevent their becoming deformed in drying, the rods are placed on pieces of sheet iron having a V-form.

The Carré carbons are more tenacious and are harder than those of retort carbon. They are remarkably accurate and regular. Rods of 0·01 mètre diameter and of 0·5 mètre length can be employed without fear of rupture. Their cylindrical form and their homogeneity make the cones maintain as perfect shape as if they were turned. They are also better conductors than retort carbons. The only inconvenience that we have remarked in their employment is a rapid disaggregation, the production of small sparks, and irregularity of the luminous brilliancy.

Gaudoin's Carbons.

M. Gaudoin also has made numerous experiments upon carbons containing foreign substances.

The following bodies have been introduced into the carbons:

1st, phosphate of lime from bones; 2nd, chloride of calcium; 3rd, borate of lime; 4th, silicate of lime; 5th, pure precipitated silica; 6th, magnesia; 7th, borate of magnesia; 8th, phosphate of magnesia; 9th, alumina; 10th, silicate of alumina.

4049 The proportions were calculated in such a manner as to obtain five per cent. of oxide after the cooking of the carbons. These were submitted to the action of an electric current always of the same direction, furnished by a Gramme machine powerful enough to maintain a voltaic arc of 10 to 15 millimètres in length.

The negative carbon being placed at the bottom, M. Gaudoin has observed the following results:

1st. The complete decomposition of the phosphate of lime under triple influence of electrolytic action, calorific action, and reducing action of the carbon. The reduced calcium goes to the negative carbon and burns in contact with the air with a reddish flame. The lime and phosphoric acid are diffused into the air, producing abundant fumes. The light, measured by a photometer, is double that which is produced by carbons of the same section cut from the residue of gas retorts.

2nd. Chloride of calcium, borate and silicate of lime are also decomposed, but the boracic and silicic acids appear to escape, by volatilisation, from the electric action. These bodies give less light than the phosphate of lime.

3rd. Silica introduced into the less conducting carbons, melts and volatilises without being decomposed.

4th. Magnesia, borate and phosphate of magnesia are decomposed, the magnesium in vapour goes to the negative carbon and burns, in contact with the air, with a white flame. The magnesia, boracic and phosphoric acids diffuse into the air in a state of vapour. The increase of light is less considerable than with the lime salts.

5th. Alumina and silicate of alumina are decomposed only with a very strong current and a very considerable voltaic arc, but under these circumstances the decomposition of the alumina is well manifested, and the alumina, in vapour, is seen to go off from the negative pole like a jet of gas, and burn with a blue flame of little lighting power.

The flame and vapour which constantly accompany these electrochemical lights having appeared to him a great obstacle to their utilisation for illumination, M. Gaudoin has not pushed these experiments farther. He has preferred to follow up his studies upon the agglomeration of carbon.

4050 The products manufactured by M. Gaudoin being superior to all others, we will expatiate a little upon this mode of manufacture.

The patent is dated 12th July, 1876.

As we have said above, the carbons intended for the production of the voltaic arc ought to be chemically pure. Thus, the dust of retort carbon, though containing only a small proportion of foreign matters, is not sufficiently pure for this use, and its employment presents some inconveniences. The washings in acids or alkalies to which the carbonaceous matters may be submitted, with the aim of extracting the impurities they contain, are costly and insufficient. Lamp-black is pure enough, but its price is high and its management difficult. Owing to this, M. Gaudoin had to seek elsewhere a better source of carbon, and he has found a solution of the problem in decomposing, by heat in closed vessels, the dried pitches, fats or liquids, the tars, resins, bitumens, natural or artificial essences or oils, organic matters capable of leaving behind carbon sufficiently pure after their decomposition by heat.

The apparatus employed to effect this decomposition are closed retorts or crucibles of plumbago. These crucibles are placed in a furnace capable of being heated to a bright red. The lower parts of the crucibles are furnished with two tubes, serving, one for the disengagement of gas and volatile matters, the other for the introduction of the primary material. The volatile products of decomposition may be conducted under the hearth of the furnace and there burnt for heating the crucibles, but it is more advantageous to conduct them into a condensing chamber or into a copper still, and to recover, after condensation, the tars, oils, essences, and hydrocarbons that are produced in this operation.

M. Gaudoin utilises these different sub-products also in the manufacture of his carbons; he takes great care to avoid for the worms and receivers the use of iron, zinc, or any substances susceptible of being attacked by these tars, because the whole value rests in purity.

Whatever may be the primary material employed for the manufacture of this carbon, the decomposition by heat should be 4051 able to be conducted either slowly or quickly according to the nature of the sub-products that it is proposed to obtain. For operating slowly it suffices to two-thirds fill the retort and to heat gradually up to a clear red, avoiding as much as possible the boiling over of the substances. For operating quickly, the empty retort is heated to a deep red, and the primary material thrown into the bottom in small quantities, in a thin stream if it is liquid, and in small fragments if it is solid. The slow distillation gives most tars and heavy oils and little gas. The quick decomposition gives more light oils and gas.

When the primary material has been properly chosen, there remains in the retort, carbon more or less compact. It is pulverised as finely as possible, and agglomerated alone or with a certain quantity of lamp-black by means of the carbides of hydrogen obtained as secondary products.

Thus prepared, those carbides are completely free from iron, and are much preferable to those found in commerce, not only in the agglomeration of the carbons, but also in the impregnation or soaking of the manufactured objects. (The last operation, by filling up the pores, introduces oxide of iron when effected with commercial products.)

The objects made in agglomerated carbon are, for one variety of carbon, as much more combustible as they are porous, and as much more porous as they are moulded with less pressure. The inventor himself uses, for his manufacture, steel moulds capable of resisting the highest pressure of a strong hydraulic press.

Although the draw-plate or moulding apparatus, used long since in the manufacture of ordinary graphite carbons, may be used, without any modification, for the manufacture of carbons for the electric light, M. Gaudoin has added to this apparatus certain important improvements. Thus instead of causing the carbons to issue from top to bottom, vertically, he places the orifice or orifices of the mould upon the side, and in such a manner that the issuing carbons form with the horizon a descending angle of 20 to 70 degrees. The carbon is guided for the whole length by tubes or gutters. This arrangement allows of emptying the whole of the matter contained
in the mould without interrupting the work, and as the car-
4052 bon is constantly supported it does not break under its own
weight, which frequently happens when issuing vertically.

We have made, at different times, numerous trials with all kinds of carbons, and those of M Gaudoin's manufacture gave the best results. It has necessitated much time and considerable expense to remove this manufacture from the merely scientific domain to that of the practical, but success has crowned the efforts of the inventor. (Table A.)

The light produced with the retort carbons was equal to 103 burners, and that produced by the artificial carbons varied between 120 and 180 burners for the Archereau and Carré carbons, and between 200 and 210 for the Gaudoin carbons. The mean of 150 burners may be applied, without appreciable error, to the Archereau and Carré carbons, and that of 205 to the Gaudoin carbons.

Brought to a uniform section of 0.0001 square mètre, the consumption of the carbons was respectively:

For retort carbons	51	millimètres.
Archereau	66	"
Gaudoin	73	"
Carré	77	"

In proportion to the light produced this consumption was:

For the Gaudoin	carbons........	35	millimètres	per 100 burners.
" Archereau	"	44	"	"
" Carré	"	51	"	"
" retort	"	49	"	"

These experiments were made with a Gramme machine constructed by M. Bréguet and a Carré lamp by the same maker. The carbons were taken at hazard from a lot of several mètres for each series.

At the request of one of the inventors we made some fresh experiments, with the co-operation of Messrs. Gramme and Lemonnier, with a more powerful Gramme machine and a Serrin lamp.

The following table (B) contains the mean of three series of experiments made with the greatest precision. The electric lamp was placed, quite vertically, at the same level as the oil-

4053 (TABLE A.)

Table of Experiments Made with Several Electric Carbons, 6th November, 1876.

Name of carbon.	Dimensions.	Speed of machine.	Consumption.				Regularity.	Observations.
			Of negative carbon.	Of positive carbon.	Total per hour.	Mean of two experiments.		
			m.m.	m.m.	m.m.	m.m.		
Retort.......	9^{mm} square.....	800	19	36	55	63	Irregular..........	Scintillating, eclipsed for a short time, a slight disaggregation.
"	9^{mm} square....	920	23	48	71		Sufficiently regular.	
Archereau....	10^{mm} diam.-....	800	20	60	80	85	Sufficiently regular.	A slight disaggregation, a few sparks. Cinders of oxide of iron in rather large quantity. White light. Cones good.
"	10^{mm} diam......	920	30	60	90		Sufficiently regular	
Carré........	$10{\cdot}4^{mm}$ diam....	800	18	60	78	92	Irregular..........	A slight disaggregation, a few sparks; more cinders than the preceding, reddened for a greater length.
"	$10{\cdot}4^{mm}$ diam....	920	26	80	106		Regular enough....	
Gaudoin.....	$11{\cdot}3^{mm}$ diam....	800	20	38	58	73	Very regular.......	Neither disaggregation nor sparks; less cinders than the Carré and Archereau carbons.

4054 lamp and photometer. Every precaution was taken that there should not be any sensible error in the measurements of the luminous intensity.

(TABLE B.)

Results of Experiments upon Several Carbons, 4th April, 1877.

Name of carbon.	Form and dimensions.	Section in square millimètres.	Total consumption per hour in millimètres.	Mean light in carcel burners.	Length of the arc in millimètres.	Revolutions per minute of the machine.	Regularity.	Observations.
Retort carbon, good quality.	Square, 9^{mm} in the side.	81	60	120	2·5	820	Passable..	Splinters numerous. Separation of a small piece. Scintillation. Carbons were shaped very irregularly.
Archereau's carbon's, new specimens.	Round, 10^{mm} diam.	78	68	173	3	820	Null......	Disaggregation. Sparks. Light very variable in intensity at periods. Shaping into small facets.
Carré's carbons, new specimen.	Round, 9^{mm} diam.	64	69	175	3	820	Middling..	Small sparks. Light running round. Very variable in intensity. Good shaping of the carbons.
Gaudoin's type No. 1.	Round, 11·2^{mm} diam.	98	80	203	3	820	Good.....	Neither sparks nor splinters. Light a little red, but pretty constant.
Gaudoin's (agglomeration of wood carbon).	Round...... ..	..	78	240	3	820	Sufficiently good.	Light very white. Less steady than with Gaudoin's carbons, No. 1. No sparks. Small variations.

4055 Brought to a uniform section of 0.0001 square mètre, the consumption of the carbons was respectively in these new experiments:

For the Carré carbons.....	44 millimètres
" retort..................................	49 "
" Archereau	53 "
" Gaudoin (wood carbon).............	61 "
" Gaudoin, No. 1........................	78 "

In proportion to the light produced, this consumption was:

For the Gaudoin (wood carbon)...	32	millimètres	per 100 burners
" Archereau	39	"	"
" Carré	40	"	"
" Gaudoin, No. 1	40	"	"
" retort	50	"	"

The light given by the Gaudoin carbons was a little less regular than that observed 6th November, 1876. That given by the Carré carbons varied in less than a minute from 100 to 250 burners; the arc rotated positively round the points, the same as if alternating currents were being used. The Archereau carbons appeared to us less effective than at the first trial; they were consumed slowly, but they produced a light so variable that it was difficult to take photometric measurements. Only the retort carbons maintained their duration, luminous intensity, and, unfortunately, their irregularity.

We shall describe, in terminating this chapter, the improvements that M. Gaudoin has made in his process, and patented, 7th April, 1877.

Instead of carbonizing wood, reducing it to powder, and then submitting it to mixture, the inventor takes dried wood, properly chosen, to which he gives the definite form of the carbon, then he converts it into hard carbon, and finally soaks it, as in the manufacture we have described.

The distillation of the wood is effected slowly, in such manner as to drive out the volatile substances, and the final desiccation is made in a reducing atmosphere, at a very high temperature. A previous washing, in acids or alkalies, removes from the wood any impurities that it possessed.

4056 M. Gaudoin points out also the means of filling up the pores of the wood, by heating to redness, and submitting it to the action of chloride of carbon and different carbides of hydrogen. He hopes thus to produce electric carbons of small consumption, and giving an absolutely steady light.

Chapter XI.

Lighting by Incandescence.

Use of Geissler tubes.—Report presented to the Academy of Sciences by M. Coste, in the name of M. Gervais.—King's invention.—Lodyguine's lamp.—Wild's report to the St. Petersburg academy.—Konn's lamp.—Bouliguine's lamp.—Experiments by the author on lighting by incandescence.—Chérémeteff and Fontaine's lamp.

As we have said, the voltaic arc is eminently convenient for the lighting of large uncovered spaces, or large halls without interior partitions, but when it is required to light small places or very subdivided localities, it is much more advantageous to employ gas, petroleum, or even ordinary oil.

There are numerous works on the construction of small electric foci, but to the present day none of the means devised have given practical results. It has been endeavoured to use Geissler tubes, and small incandescent carbons, and if these two means have not been successful, they offer nevertheless sufficient interest that we should devote some pages to their description.

It is well known that Geissler, an artist at Bonn, constructed the first tubes blown in various forms, closed hermetically and containing only traces of various vapours. These tubes put into communication with a current, by means of platinum wires fused into the glass, from a Ruhmkorff coil, produce a stratified light, that is to say, composed of fine transverse layers separated by dark layers continually agitated. At the same time the sides of the tubes present a brilliant appearance, to which the term fluorescence has been applied.

On March 27, 1865, M. Coste presented to the Academy of Sciences, in the name of M. Gervais, the following report:

"The apparatus was constructed by M. Ruhmkorff, who has acquitted himself of his task with his usual care and ability. It is a case or box in bronze, mounted on four feet, and its cover 4058 or lid is hermetically closed by means of a press-screw, and between the two surfaces thus brought into contact is a caoutchouc washer. To the cover is attached a ring, serving as a suspension to the optical apparatus. The case contains two bichromate of potash elements closed in their turn by plates to which strips of copper are solidly screwed. The poles of the current furnished by these two elements may be put at will into communication with the bobbin, and the induced current is transmitted to a Geissler tube by two wires covered with India rubber. This tube, of proper form and filled with carbonic acid, is enclosed in a glass cylinder with thick sides, furnished with copper armatures, and into which water cannot penetrate. This is the lighting part of the apparatus. With this instrument a soft light is obtained, similar to that now employed by miners. It resembles in certain respects that given by phosphorescent animals, but is more intense. It can be seen even when the apparatus is several mètres under water. It would doubtless serve to attract fish, as does the phosphorescence of certain species, and it would also serve to light limited spaces, situated beneath the surface of the water, or by floating signals. The captain of the 'Devoulx,' commanding the southern coasts of France, employed this apparatus in the port of Cette, in September last. It remained immersed for nine hours, and it gave light for six hours, under these conditions, as well as when charged at Montpellier. The phosphorescence may be of longer duration. A second trial, made at Port Vendres, on board the 'Favori' (Captain Trotabas), was equally successful."

The light obtained by the Geissler tube is so feeble, that it can never be utilised practically, and numerous trials made in mines and powder mills have been without result.

Lighting by incandescence has been studied for a long time; but its application generally presents so great difficulties, that at the present day it may be considered as within a purely scientific domain, although a certain number of apparatus exist working moderately well.

The first document on the question that we have found, is an English patent of the 4th November, 1845.

Mr. King, the inventor, enters into some exact details of his
4059 idea, and presents some considerations which tend to prove
that magneto-electric machines, powerful enough to produce
light, already existed in 1845.

The following are the principal passages from this patent:

The invention has for its basis the use of metallic conductors, or of continuous carbons, heated to whiteness by the passage of an electric current. The best metal for this purpose is platinum, the best carbon is retort carbon.

When carbon is employed, it is useful on account of its affinity for oxygen at high temperatures to cover it from air and moisture, as indicated in Fig. 45. The conductor C rests on a bath of mercury; the bar B is in porcelain, it serves to support the conductor C; the conductor D is fixed on the bell by a hermetically sealed joint. The carbon rod A rests at top and bottom on conducting blocks and becomes incandescent by the passage of an electric current.

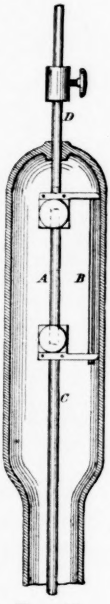

FIG. 45.
King's Lamp.

A vacuum is previously established in the bell, and the apparatus veritably forms a barometer with one of the poles of the battery in communication with the column of mercury, and the other with the conductor D.

In order to obtain an intermittent light, the circuit can be periodically interrupted by a clock-work movement.

The apparatus properly closed may be applied to submarine lighting, as well as to the illumination of powder mills and of mines, especially where the danger of explosion is feared, or the rapid inflammation of very combustible substances.

When the current is of sufficient intensity, two or a larger number of lights may be placed in the same circuit, care being taken to regulate the power of the magneto-electric machines, or the elements of the battery producing the current.

In 1846, Greener and Staite filed a patent for a lamp,
analogous to King's, pointing out that they freed
4060 the carbon, before use, from impurities by treat-
ment with nitro-muriatic acid.

In 1849, Petrie concludes the description of a patent for a lamp with the following remark: "A light may be produced by passing an electric current through a short and thin conductor, which heats and becomes luminous; but the majority of substances fuse and burn rapidly; however, I obtain a good light by using iridium, or one of its alloys. Iridium may be fused so as to produce an ingot whilst it is submitted to the heat of the voltaic arc; afterwards it may be decarbonised and rendered more malleable. It can be cut into small pieces of 0·001 mètre diameter and 0·010 to 0·020 mètre length, that can be fixed upon two insulated metallic supports, which are in connection with the two wires of a proper galvanic battery. There is then obtained a beautiful light."

Several other patents have been taken out in America, France, and England for the same kind of idea; but none of these appear more complete, more explicit, and more practicable than King's; it is then useless to continue our nomenclature.

Lighting by incandescence, and the principle of its production, had for a long time fallen into oblivion, when in 1873 a Russian physicist, M. Lodyguine, resuscitated both, and invented a new lamp, which has since been perfected by Messrs. Konn and Bouliguine.

In 1874, the St. Petersburg Academy of Sciences awarded a high prize to M. Lodyguine. The following includes some extracts from the report presented on the occasion by M. Wild, director of the Imperial observatory; this report, as we shall see, includes several capital errors:

"It has long been known that we can employ the heating faculty of the electric current, even without the aid of gas, as in the luminous galvanic arc, to heat a solid body to whiteness. On this principle there are often thus heated thin platinum wires, which are bad conductors, by causing them to be traversed by a powerful electric current. The light obtained by this process is much more feeble and more constant than the electric light from carbon; it can also be extended further, and may be increased or diminished at
4061 will; nevertheless it has never found practical use, because
it is too feeble compared with its cost, and because when it is desired to give greater intensity, there results fusion of the platinum wire, which in general is not homogeneous throughout.

"M. Lodyguine was the first who had the idea of replacing the platinum wire, in these combustion experiments, by small bars of carbon (coke) analogous to graphite, that is to say, a good conductor, and thus resolved the problem of electric lighting.

"The advantages of this substitution of the carbon for platinum are so obvious from a theoretical point of view, that it is astonishing, as is always the case with important inventions, that no one had the idea sooner. Carbon possesses at equal temperature much greater power of radiation than platinum; the capacity for heat of platinum is superior (nearly double) that of the carbon in question, so that the same quantity of caloric raises the temperature of a small bar of carbon to a degree nearly twice that attained by a platinum wire of the same volume. Besides the resistance of the carbon in question, as a conductor of electricity, is nearly 250 times greater than that of platinum; it results that the small rod of carbon may be fifteen times thicker than a platinum bar of the same length, and that the current traversing it will engender the same quantity of heat. Finally the carbon may by heated to the most extreme white heat without fear of fusion, as is the case with plati-

num. It is to these important theoretical advantages that is evidently due the great success of the mode of electric lighting proposed by M. Lodyguine.

"The sole inconvenience of the use of carbon instead of platinum consists in the fact that, in the combustion the carbon combines with the oxygen of the air, and is thus gradually consumed. M. Lodyguine has avoided this inconvenience by enclosing the carbon heated to whiteness by the electric current in a glass receiver hermetically sealed, and from the interior of which the oxygen is expelled by a most simple process.

"It is not within the province of the Academy of Sciences to give its judgment on the technical and other difficulties which will present themselves in the extended application of M. Lodyguine's invention, nor, on the other hand, upon the numer-
4062 ous practical advantages of this mode of lighting above all others; it will suffice to the academy to state that, thanks to this invention, there is resolved in the simplest possible manner the great problem of subdivision of the electric light, and of rendering it constant,* in order to recognize M. Lodyguine as worthy, in consideration of the numerous applications of his invention, to obtain the Lomonossow prize."

In his lamp, M. Lodyguine employs carbon in a single piece by diminishing the section at the point of the luminous focus, and he places two carbons in the same apparatus with a small exterior commutator, in order to pass the current into the second carbon, when the first has been consumed. Nothing is less practical nor less studied than the apparatus of this inventor.

M. Kosloff, of St. Petersburg, who went to France in the hope of working the Lodyguine patent, perfected his lamp slightly, without, however, bordering upon anything passable.

In 1875, M. Konn, also from St. Petersburg, patented a more practicable lamp, represented in Fig. 46, which was constructed for the first time in Paris by M. Duboscq.

(Here follows diagram marked p. 4064.)

This lamp consists of a base A in copper, on which are fixed two terminals N for fastening the conductors, two bars C, D in copper, and a small valve K opening only from within outwards. A globe B, widened at its upper part, is retained on the base by means of a bronze collar L pressing on an India-rubber ring, exactly as occurs with the level gauges of steam boilers.

One of the vertical rods D is insulated electrically from the base, and communicates with a terminal also insulated. The other rod C is constructed in two parts: (1) Of a tube fixed directly upon the base without insulation, and (2) of a copper rod split for a part of its length. This split gives elasticity, and admits of the rod sliding in the tube with only a small effort.

---

* We shall see subsequently how the problem has been resolved by M. Lodyguine.

The retort carbons E, to the number of five, are placed between two small plates which crown the rods.

Each carbon is introduced into two small blocks, also of carbon, which receive the copper rods at their extremities. The rods also
are equal in length at their lower ends, and of unequal length
4063 at their upper ends. A hammer I is hinged on the bar C, and
rests only on a single rod of carbon at once. If this lamp is placed in circuit by attaching the two conductors from a battery to the terminals N, N′ (the terminal or binding screw N′ is hidden by the terminal N; but it is identical, and is not insulated from the base), the bar of carbon E is traversed by the current which passes by the aid of the hammer I, from the copper bar F, the two carbon blocks O, O, the copper bar G, and the plate crowning the bar D.

The vacuum has previously been made by putting the cock K in connection with an air pump or other known pneumatic machine.

The rod E reddens, whitens, and becomes luminous. Its light is colourless, steady, and constant; but gradually the section diminishes, the rod breaks, and the light disappears. The hammer I then falls on another rod, and nearly instantaneous*ly* lighting is re-established.

When all the carbons are consumed the hammer rests upon the copper rod H, and the current is not interrupted. In this manner when several lamps are fed by the same electric generator, extinction of one does not cause that of the others.

To avoid the projection of small pieces of carbon and their block against the glass, M. Konn has placed at the lower part of his lamp a small copper tube M, which received the débris until the plates are refurnished.

Three of these lamps were introduced two years ago at the house of M. Florent, a merchant of St. Petersburg, and put in action with an "Alliance" machine. Each carbon lasts about two hours, with the exception of the first, which is consumed nearly immediately; the light is very agreeable, but its cost considerably exceeds that of gas. M. Florent, whom we have had occasion several times to see, has informed us that the great advantage he has found in the employment of electric lighting was its cleanliness. His store-rooms contain much white linen that gas rapidly impairs, and on which electricity exercises no injurious influence. The bleaching economised fully compensates the supplementary cost necessitated by an important introduction, with but little regard to the light obtained.

M. Florent has not made any photometric measurement;
4065 but, by comparison with gas, each Konn lamp has been
valued at about 20 Carcel burners.

The principal cause of the great expense that the use of the light from incandescence entails, rests in the difficulty of preparing small carbons, which cost, as fitted, more than 5 francs per mètre.

A Russian officer, M. Bouliguine, has constructed a lamp (Fig. 47), which attains nearly the same end as that by M. Konn with a single carbon. It consists, like the preceding, of a copper base or

No. 286.
C. E. Light Co.
v.
McK. Light Co.
p. 4066

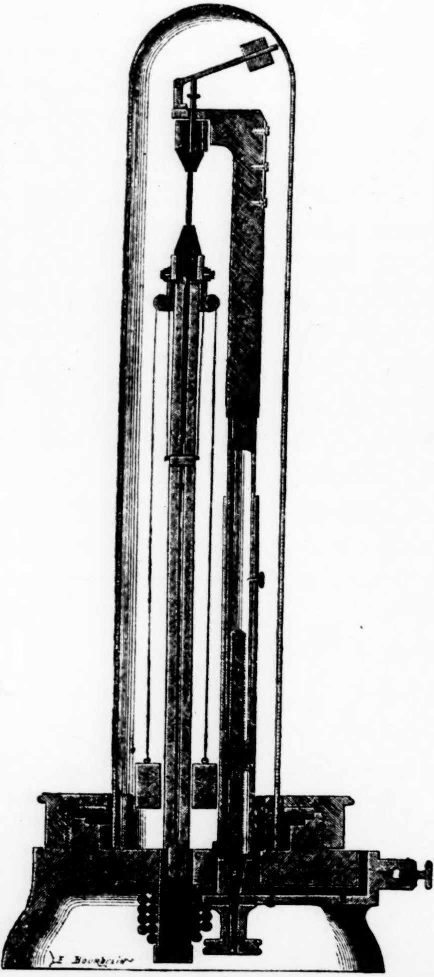

FIG. 47. BOULIGUINE'S LAMP.

socket, two vertical bars, two bars carrying the current, and an exhaust valve.

(Here follows diagram marked p. 4066.)

One of the bars is pierced with a small hole from top to bottom, and has nearly throughout its length a slot admitting the passage of two small lateral lugs.

The carbon is introduced into this bar like the lead of an ordinary pencil case, and it is assisted to rise by a counter-weight connected by two microscopic cables to lugs in the transverse support on which the carbon rests.

The part of the carbon which is to become incandescent is held between the lips of two conical blocks of retort carbon.

A screw placed on the base admits of increasing or diminishing the length of the bar which carries the upper conical block, and consequently of giving to the luminous part greater or less length.

The closing of the globe is effected by the lateral pressure of several India rubber washers.

When the lamp is placed in circuit, the carbon rod reddens and illuminates until it is about to break. At this moment a small mechanism* commanded by an electro-magnet opens the lips of the carbon-holders, the counter-weight above drives out the fragments that would remain in the notch, and the counter-weight below raises the carbon rod which penetrates the upper block, and re-establishes the current. The mechanism again acts, but in contrary direction to its first manœuvre, the carbon-holders contract, and the light is renewed.

4067 We have several times tried this lamp, but we have never obtained good results. It includes too many moving parts, and the least obstacle prevents the play of the mechanism. However, we have observed that when by chance it works regularly, the contacts being better and less numerous than those of Konn's lamp, it needs less intense currents for the production of a given light. With a Gramme machine of 100 burners we have obtained with a single lamp as much as 80 burners, whilst with a Konn lamp we could never exceed 60 burners.

In order to realise the actual value of the system of lighting by incandescence, we have made a series of experiments with several Konn's lamps and a Bunsen battery of 48 elements, of 0·20 mètre height.

The first operation consisted in measuring the resistances of retort carbon of square section. The samples tested were 0·002 mètre in the side. The following results are from eight experiments:

---

* The mechanism in question, which the scale of the engraving will not admit of showing, consists substantially of an iron armature placed in the interior of the lamp, and of two metallic rods acting on two cross-levers jointed onto the ring surrounding the carbon-holders.

Number of experiment.	Length of samples.	Resistance in mètres of telegraph wire.
	Mètre.	
1	0·100	16
2	0·100	14
3	0·100	15
4	0·100	14·50
5	0·100	19
6	0·050	7
7	0·050	9
8	0·050	7
Total	0·650	101·50

Whence it results that the mean linear resistance of the retort carbon of 0·002 mètre is about 172, that of a telegraph wire of 0·004 mètre being taken for unity.

We subsequently rounded the carbons, so as to reduce their diameters to 0·0016 mètre, and regulated the length in such a manner as to obtain 0·018 mètre incandescent part. The vacuum was carried to about 0·70 mètre mercurial pressure.

The following results represent the mean of more than twenty series of experiments:

4068

State of the circuit.	Methods of coupling the battery.							
	2 series parallel of 24 elements.		3 series parallel of 16 elements.		4 series parallel of 12 elements.		1 single series of 48 elements in tension.	
	Galvanometer deflection.	Luminous intensity of each lamp.	Galvanometer deflection.	Luminous intensity of each lamp.	Galvanometer deflection.	Luminous intensity of each lamp.	Galvanometer deflection.	Luminous intensity of each lamp.
Circuit closed on itself.	47	....	70	....	70	....	50	
5 lamps...	28	Reddish-white	17	Cherry red.........	10 or 11	Dull red..........	35	½ burner
4 lamps...	29	½ burner.........	22	Reddish-white...	16	Orange-red	38	2½ burners
3 lamps...	38	1 to 2 burners..	28	1/3 burner	26	¼ burner.........	41	3½ burners
2 lamps ..	40	3 burners	41 to 42	2½ to 3 burners...	40 to 45	3 to 5 burners..	44	5 burners
1 lamp.....	43	4 to 5 burners..	49	11 to 12 burners..	60	40 burners.....	45 to 46	6½ to 7 burners

The lamps were grouped like the elements of a battery in tension, then forming a single series.

In the following table are given the results obtained with lamps arranged in batteries, that is to say, on distinct circuits derived from the battery. Because of the considerable differences observed in the intensities of the light of each lamp during the same experiment, we give the total light instead of that produced by each lamp:

State of the circuit	Methods of coupling the battery.							
	2 series parallel of 24 elements.		3 series parallel of 16 elements.		4 series parallel of 12 elements.		8 series parallel of 6 elements.	
	Galvanometer deflection.	Total light emitted by the whole of the lamps.	Galvanometer deflection.	Total light emitted by the whole of the lamps.	Galvanometer deflection.	Total light emitted by the whole of the lamps.	Galvanometer deflection.	Total light emitted by the whole of the lamps.
Circuit closed on itself.	58½	....	68	....	69	....	70	
5 lamps..................	57	....	64½	¼ burner......	63½	2½ burners...	60	
4 lamps..................	56½	....	63	¾ burner.....	63	3 burners.....	59	
3 lamps..................	56	1 burner......	61½	2 burners.....	62	4 burners.....	58	¾ burner
2 lamps..................	55	5 burners.....	60	6½ burners...	59	15½ burners..	55	1½ burner
1 lamp..................	52½	9 burners.....	57½	54 burners...	55	65 burners...	46	8 burners

Several important observations were made during these experiments.

When the receivers are sealed and the contacts carefully put in line, the carbons last for a satisfactory period. The first carbon of a lamp never lasts for less time than a quarter of an hour; 4069 sometimes it breaks at the end of thirty to thirty-five minutes, but that is very rarely; its average duration is twenty-one minutes. The succeeding carbons last upon an average for two hours, so long as the luminous intensity does not reach 40 burners, in which case the average duration is only half an hour. In the experiment of four parallel series of 12 elements, the five lamps being collected in batteries and one only lighted, the carbon, which gave 65 burners, lasted only twenty-three minutes as an average.

Attentive examination of incandescent carbons, through a strongly coloured glass, has shown that they are not uniformly brilliant. They present obscure spots, indicative of non-homogeneity, and the position of cracks which rapidly disintegrate the carbon.

The vacuum never being perfect in the receivers, the first carbon is in greater part consumed. It would appear that consequently upon the little oxygen contained in the lamp being transformed into carbonic acid and carbonic oxide, the carbon should be preserved indefinitely. But there is then produced a kind of evaporation which continues to slowly destroy the incandescent rods. This evaporation is besides clearly proved by a pulverent deposit of sublimed carbon, that we have found on the interior surface of the bells, on the several interior parts: rods, contacts, hammers, &c.

No bell has been cracked by heating or cooling during the whole of the experiments, extending over several months, but several of the necks have been broken by the too energetic closing of the joint.

The delicate part of the lamp is in the series of contacts which precede the incandescent rod. The carbons are got into straight line, which is indispensable to their duration, only with minute and long precautions. After rupture, the contact does not always occur automatically, and two or three times we have been obliged to shake the lamp to cause the lighting of the next carbon.

The maximum efficiency has occurred with a single lamp and with four elements in quantity; by employing two lamps and descending to two elements in quantity, the results were considerably diminished.

4070 We have recently made similar trials with Gaudoin artificial carbons of the same section, and the results have been more satisfactory. Thus the total light produced with 48 elements in four series and a single lamp, reached 80 burners, and that produced with the same battery and three lamps, attained 30 burners.

The same battery coupled in tension and actuating a Serrin lamp gives a voltaic arc of 105 burners; but the light obtained by incandescence is much steadier and more agreeable to the eye.

From what precedes, it appears to result that King and Lodyguine's system is much more favourable to large foci than to the divisibility of the electric light; however it is proper to remark that when 10 burners per lamp are not exceeded, the carbons have a very long duration, whilst they are consumed very quickly for an intensity of 60 to 80 burners.

Only carbons of 0·0016 mètre diameter and 0·018 mètre luminous length were until then those tried; these behave very well with a strong current, but give no light with 12 elements. It became interesting to learn what light could be obtained with 12 elements by diminishing the length of the carbons. This was the object of a new series of experiments.

Five different combinations were attempted, by varying in turn the coupling of the battery, the diameter of the carbon and its length.

The best results were obtained with a single lamp furnished with Gaudoin carbons of 0·0016 mètre diameter, and of 0·015 mètre length, in the incandescent portion.

The light varied between 2 and 8 burners, but it was more often 5 burners. Each carbon lasted on average fifteen minutes.

We were about to repeat all these experiments, substituting for the battery a Gramme machine constructed to give the best useful effect; but the imperfections of the lamps, the difficulty of obtaining good contacts, the too minute care to be taken at the commencement of each operation, led us to decide to previously design a lamp more commodious and slightly more practical than that of M. Konn.

4072 This lamp, which we represent in Fig. 48, is at present under construction by M. Bréguet. It is characterized by the two following points: (1) the carbons are set in a groove at each of their extremities in rigid contacts and kept fixed, which admits of the lamp being placed in all positions; (2) the electric current passes automatically from one carbon to the other by the action of an electro-magnet interposed in the circuit.

(Here follows diagram marked p. 4071.)

A description, even summary, would not be of great interest, since the lamp is not yet finished; the engraving sufficiently indicates the arrangement we have adopted.

UNITED STATES PATENT OFFICE.

WILLIAM E. SAWYER, of New York, N. Y., assignor to Electro Dynamic Light Company, of New York.

Dynamo-Electric Machine.

Specification forming part of Letters Patent No. 237,632, dated February 8, 1881. Application filed December 20, 1878.

To all whom it may concern:

Be it known that I, William Edward Sawyer, of the city, county, and State of New York, have invented a new and improved dynamo-electric machine, of which the following is a description in such full, clear, concise, and exact terms as to enable any person skilled in the art or science to which it appertains or with which it it is most nearly connected to make and use the same, reference being had to the drawings accompanying and making part of this specification, and to the letters and figures of reference marked thereon, as hereinafter described.

The object of this invention is to simplify the construction, increase the efficiency, and decrease the resistance, and heat of the dynamo electric generating-machine.

Said invention consists, first, of a generator of electricity operating through the increasing and decreasing magnetism in the magnets by the approach and recession to and from the magnets of paramagnetic armatures; second, of a generator operating by the shifting of the magnetic force from and into different parts of the magnets; third, of a generator in which only the magnets are wound with the conducting-wire, thus avoiding the retarding effects which take place when both magnets and armatures are wound, as in the case of other dynamo-electric machines employed for electric lighting and electrolysis.

(Here follow diagrams marked pp, 4073 & 4074.)

Reference being had to the drawings, figure 1 is a side elevation of the generator with the disk K removed. Fig. 2 is a transverse vertical section through the same. Fig. 3 is a view of the annexed commutator developed, and Fig. 4 is an end view of the commutator wrapped around a rotating drum annexed to the generator.

The generator consists substantially, of the following principal parts:

First, of two rings, (shown in Figs. 1 and 2 of the drawings by H H.) To these rings are fitted a series of electro magnets or permanent magnets, A A A, projecting inward in the manner shown, the north pole of each magnet being connected to one of said rings, and the south pole to the other. One ring is therefore the north pole and the other the south pole of the entire machine.

Second, of two flanges or disks, K K, bolted to the magnets A, by which said rings and magnets are held in position around a center common to themselves, and the disks K, which are supported and held by legs I I, bolted to any suitable frame.

Third, of a barrel or cylinder, B, fitted with armatures G. This cylinder or barrel, with its armatures, rotates upon the center shaft, C, fitted into and carried by the hubs of the flanges K, the periphery or shell of the cylinder being supported by spokes D, as shown in the drawings.

The rings H are provided with projections F, arranged upon a common circle with the lower ends of the magnets, and between these projections and the poles of the magnets proper are coils of wire, S, creating an electro-magnet on the ring each side of the magnets A, the ring being thus converted into a succession of electro-magnets over the armatures G, which are, of course, arranged to swing clear of the projections F and the lower ends of the magnets A.

The operation is as follows: If A A are electro-magnets, as shown by the drawings, they will contain a slight residual magnetism. The armatures G, being in the position shown, satisfy the magnetic attraction of the magnets, and little or no magnetic force exists in the intermediate parts of the rings H, which are embraced by S F S. Now, as the armatures G come opposite the projections F on the rings, these projections become the poles of the magnets, and the magnetic force thus sent into the interior of the coils S generates currents in these coils, which being thrown by the commutator around the magnets A through the coils U, in the well-known manner, further magnetize them, until finally they are magnetized to saturation by the well-known process of accumulation.

The commutator shown by Figs. 2, 3, and 4 consists of two rows of insulated pieces, O O, connected interchangingly, as shown by Figs. 2 and 3. These pieces are fixed to an insulating drum, L, fitted on the sleeve M, carried by the shaft C. Upon this drum L are fitted two insulated rings, R R, connected to the pieces O O, as shown by Figs. 2 and 3 of the drawings, and upon the rings
4076 R and pieces O ride four springs, N N and N′ N′. Now, the
coils S are wound alternately in opposite directions to accord with the winding of the magnet-coils U and all the coils form one conductor, the two ends of which (shown by X Y) are connected electrically to the two outside springs, N N. The current in these coils is set straight by the two inner springs, N′ N′, being upon the pieces O. To one of springs N′ the external conductor Z is connected, and to the other spring N is connected one end of the conductor which constitutes and leads from all the coils U. The other end of the wire constituting the coils U forms the other pole of the external conductor, in which is placed the electric light or other apparatus to be worked. The tension of the springs N and N′ is adjusted by the screws P, substantially as shown by the drawings.

In concluding this description of my invention, I desire to say that I do not intend to limit the patent of which this specification is to be a part to any particular form of the invention or any part thereof, but intend to claim the principle or substance of that form—that is to say—

I claim—

1. A dynamo-electric generating-machine constructed of stationary magnets in which the magnetic force is continuous, such magnets being surrounded with conducting-coils, in combination
4077 with a rotating barrel of unwound armatures, as distinguished from the stationary magnets, and rotating barrel of armatures of electro-magnetic engines, in which the magnets are energized intermittently to produce motion.

2. The combination of the magnets A S F, connected and operating substantially as described.

3. The two rings H H connected by magnets and operating substantially as described.

4. The combination of magnets A, rings H, and armatures G, operating substantially as described.

5. The combination of a series of contiguous magnets, A, with a series of intervening sections of iron joining their poles over a rotating armature, substantially as described, for the purpose of inducing and accumulating their magnectic force, substantially as set forth.

6. A dynamo-electric generating-machine, consisting of united rings fitted with a succession of electro-magnets and combined with a succession of armatures rotating about a centre common to themselves, and the series of magnets.

7. In a dynamo-electric machine, a succession of electro-magnets fitted and connected upon stationary rims or rings and energized by a succession of unwound armatures rotating with the rims carrying the magnets.

Dated December 16, 1878.

UNITED STATES PATENT OFFICE.

S. GARDINER, JR., and L. BLOSSOM, of New York, N. Y.

Improved Electric Signal-Light.

Specification forming part of Letters Patent No. 20706, dated June 29, 1858.

To all whom it may concern:

Be it known that we, Sam'l Gardiner, Jr., and Levi Blossom, of the city, county, and State of New York, have invented a new and useful electric signal lantern or light; and we do hereby declare that the following is a full, clear, and exact description of the same, reference being had to the accompanying drawings, forming a part of this specification, in which—

(Here follows diagram marked p. 4078.)

Figure 1 is a front view of a signal lantern or light constructed after our invention. Fig. 2 is a vertical longitudinal section of the same. Fig. 3 is a vertical transverse section of the same. Fig. 4 is a diagram illustrating a modification of our invention.

Similar letters of reference in each of the several figures indicate corresponding parts.

The nature of our invention consists in the combination of a platinum coil or its effective equivalent, which is illuminated by electricity, with a transparent signal-lantern, said combination being effected by arranging the coil within the lantern upon two conducting-wires which are connected with an electro-galvanic battery.

To enable others skilled in the art to make and use our invention, we will proceed to describe its construction and operation.

A represents a standard for supporting a signal-lantern, B, adapted for carrying out our invention successfully. This lantern has two or more of its sides formed of colored glass, one side being blue and the other red, or otherwise illuminated so as to be seen readily at a great distance. The central portion of the transparent sides is not colored, as shown at *a*, so that the intense light directly about the platinum coil may not be shaded, or be partially obscured. The lantern is provided with suitable reflectors, *b b*, and is ventilated by means of holes *c c* and spaces *d d* around the edges of the glass, as illustrated by the arrows.

C is the platinum coil. It should have the form of a circle and be arranged opposite the central uncolored portions, *a a*, of the glass sides, as shown. This coil rests upon two conducting-wires, D D, which extend down from the interior of the lantern to the battery, which is situated in the lower or any convenient part of the hull of the vessel, and is connected with a telegraphing-machine, so that the electric illuminating-current may be let onto the platinum coil or shut off from it at pleasure.

S. GARDINER, Jr. & L. BLOSSOM.

Electric-Signal Light.

No. 20,706. Patented June 29, 1858.

No. 286.
C.E. Light Co
v.
McK. Light Co
p. 4078

Fig 4

Instead of having the conducting-wires extend down to the battery, they may be cut off so as to just touch the base-plate *d* of the standard of the lantern. In this case said plate must be connected with the battery and be insulated at two points on its surface, in the manner shown at *e e*, Fig. 4, and the lantern and standard arranged to revolve.

By our invention the most intense and brilliant light can be constantly kept up, as the electric current is concentrated by the platinum coil in a manner that said coil will always be heated to the color of a brilliant white flame, which will be seen at a great distance through the unshaded central part of the lantern, and its reflected rays through the colored portions of the transparent front.

With our invention any desired signals may be transmitted from one ship to another, as follows: We will suppose that the captains of different ships have agreed between themselves that the appearing and disappearing of the signal-light twice shall indicate "distress," the appearing and disappearing of the light three times, "all right," and so on. Now, to accomplish these signals all that is necessary is for the captain or other person in charge of the matter to touch the keys of the telegraphic-machine the proper number of times and in the proper manner.

In case the signal-lantern is arranged to revolve, the same signals can be produced by the breaking of the current at intervals, which is effected by having the conducting-wires come at intervals in contact with the insulated portions of the base-plate.

The signal-lantern has two of its sides formed of different-colored glass, so that when used on a buoy the electric light may be seen by ships coming in and going out to sea.

The value of a sure signal-light cannot be estimated when the important office it is to serve is considered. We believe our signal-light can be depended upon, both as to its great intensity and as to its certainty of remaining always in force, there being no possible chance for it to cease so long as the battery is supplied and the electric current conducted to the platinum coil.

4080 This invention is perfectly applicable to the purpose of signal-lights on board of boats, ships, vessels, and buoys; also to stationary signals on land for military and scientific purposes; also for all stationary or floating light-houses for coasts and harbors.

What we claim as our invention, and desire to secure by letters patent, is—

The combination of a platinum coil, C, or its effective equivalent, which is illuminated by electricity, with a transparent signal-lantern, B, said combination being effected by arranging the coil C within the lantern B upon two conducting-wires, D D, which are connected with an electro-galvanic battery.

UNITED STATES PATENT OFFICE.

STEPHANE ALEXANDROVITCH KOSLOFF, of Paris, France.

Improvement in Electric Lights.

Specification forming part of Letters Patent No. 166,877, dated August 17, 1875; application filed June 23, 1875.

To all whom it may concern:

Be it known that I, Stephane Alexandrovitch Kosloff, of Paris, in the Republic of France, have invented an improved electric lamp; and I do hereby declare that the following is a full, clear, and exact description of the same, reference being had to the accompanying drawing, which forms part of this specification.

My invention relates to certain improvements in that class of apparatus for the production of electric light wherein an electric current passes through and heats sticks of carbon placed in the circuit and hermetically closed in a globe filled with nitrogen-gas, and the object is to avoid several disadvantages heretofore existing.

Heretofore it has been usual to place the carbon on metal conductors, which served as supports, and were firmly attached to the carbons either by screws or otherwise. This joining together of two non-homogeneous substances, subject to different temperatures, caused the breakage of the carbon because of its not dilating in the same ratio as the metal, or because the dilatation of the metal was greater than that of the carbon, and the metal in heating detached itself gradually from the carbon and produced electric sparks. To remedy this difficulty one part of my invention consists in placing the carbon between two insulating-supports composed of porcelain, clay, glass, calcined magnesia, or other insulating substance, so arranged as to allow a slight movement of the carbon in the supports.

Another part of my invention relates to a means for preventing a difficulty which arises in cases where the metal is outwardly attached to the carbon in any way, in consequence of which the metal detaches itself in heating, and produces electric sparks and becomes melted. This part of my invention consists in introducing the metal into the carbon, whereby I obtain a better contact when the carbon is heated by the current, and also prevent the production of electric sparks; but in order to avoid putting the metal into direct contact with a white-heated carbon, I use thicker pieces of carbon provided with holes through their length and their thickness, which thicker pieces serve as conductors of the electric current, and not being such poor conductors as the thin sticks of carbon with which the light is to be produced, and which are introduced into the thicker pieces, heat to a less degree the metal introduced into them.

Another part of my invention consists in connecting the principal conductors with the metallic wires, which are inserted into the thick pieces of carbon by means of links of fine twisted wire, whereby sufficient motion is allowed them when in a state of dilatation, and whereby sufficient contact is insured without producing electric sparks. This mode of connection does not increase the loss of electric current, because the heat produced by an electric current passing through two pieces of metal not firmly attached to each other, but closely touching each other, is much smaller than the heat caused by contact with a white-heated body in a high temperature.

Another part of my invention relates to means for avoiding the inconvenience of the preparation of nitrogen gas and its introduction into the lamp after the air has been withdrawn from it; and it consists in the method of rarefying the air in the globe by means of the carbon which is heated by the electric current and produces the light. By dilating the air it is caused to escape out of the globe through a cup-valve surrounding the supporting column upon which the globe rests, which valve prevents the air from again entering the globe. The small quantity of oxygen remaining in the rarefied air in the globe is transformed into oxide of carbon. In order to have as little air as possible in the globe, I make the supporting column nearly as large in diameter as the globe itself, so as to reduce the dimensions of the air-space, and also of sufficient height to enable it to support the bearers carrying the sticks of carbon which produce the light. The supporting column is made of porcelain, clay, calcined magnesia, crystal, or other suitable insulating substance, provided with tubular openings or grooves for the passage of the metallic conductors, or of carbon furnished with insulators, when such conductors are used instead of metallic ones. The supporting column may be made of metal, if de-
4083 sired; but in such case it should be provided with insulators, in order that the currents may meet in the sticks of carbon. The globe and supporting column are of sufficient length according to the strength of the light to be produced, to prevent the valves from being exposed to too great a heat, and to allow of the employment, as a hydraulic closing, of any liquid, which, being exposed to a certain heat, will not produce vapors which will consume the carbon. For this purpose I entirely avoid the use of mercury.

Another part of my invention relates to a mode of overcoming a difficulty which may arise where the electric current is not sufficiently strong to heat a thick stick of carbon; and it consists in the employment of a number of thin sticks of carbon, arranged so as to be heated successively, and to provide for the automatic passage of the electric current from one to another. The wires which traverse the thick pieces of carbon may be inserted not at the same height, but one slightly lower than the next preceding one. In case of breakage of one of the thinner portions the large or thick end, being fastened on one side only, will incline toward the link or ring connection of the second carbon, and, by means of its hook-shaped wire or plate, is placed in connection with said second carbon, and the current being interrupted in the first carbon is communicated to the second; and this operation is repeated in case of the breakage of the second or any succeeding carbon. In lamps containing several carbons the insulators, between which the thick or large ends of the carbons rest, are of rounded form, with small openings, provided with means for preventing said thick ends from descending too low. In such lamps one pole is in communication with the lower ends of all the carbons, and the other pole communicates with the carbon, which is to be lighted first—that is, the one in which the metallic wire is placed at the highest point.

When it is not desirable to use the automatic mechanism in lamps containing several carbons I employ a commutator, where one pole is in communication with the lower end of all the carbons, while the other pole may be put into communication with each series of carbons in different lamps having separate conductors. The placing of the lamps in the circuit may be effected in two ways—namely, either by placing one series of lamps united by a metallic wire, in such a manner that the current will traverse all the carbons, the conductor of one pole being in communication with the first lamp, and the conductor of the other pole being in communication with the last lamp, or by subdividing the current—that is to say, the current from one pole is subdivided from one point and conducts the current by separate conductors to each lamp, and the current of the other pole subdivided in the same way meets the current of the first pole in each lamp.

In order to enable those skilled in the art to which my invention appertains to more fully understand the same, I will describe in detail the accompanying drawing, in which—

(Here follows diagram marked p. 4081.)

Figure 1 is a sectional elevation. Fig. 2 is a perspective view of the upper end. Fig. 3 is a sectional view taken in the line 1 2 of Fig. 1. Fig. 4 is a sectional view taken in the line 3 4 of Fig. 1.

a represents a vertical supporting rod; *b*, nuts for retaining the insulating-plate; *c*, insulating-plate, having four holes for the passage of metallic pins; *d*, large ends of carbon, bored throughout their whole length and thickness by a drill of the same dimensions as the carbon *f* and of the wires *e* inserted into these large ends; *e*, hooks; *f*, carbon pins driven into the large ends, and intended to produce the light; *g*, conductor of one pole; *g'*, conductor of the other pole. These two conductors are of copper, and may be silvered or platinized. They are inserted in a groove in the column *h*, except in the lower part, which allows vulcanized india-rubber to pass between the insulating-piece and the metal conductors, which may be afterward bound with metallic wires. *h*, a column of porcelain or other suitable substance, serving as a support, and also to leave the least possible air in the globe; *i*, porcelain or other ring, having a hole in it, and serving as the base of the apparatus, and provided with grooves for the passage of the conductors *g* and *g'*; *j*, porcelain basin or bowl, the cover of which is bored for the passage of the glass globe *k*, which rests on the piece *i*, and is kept steady by springs *l*. The bowl *j* has holes, through which pass the exterior conductors *m m'*, which are connected with the interior

conductors g. n, a leather ring, cupped in the form of a valve, allowing air to pass out of the globe, but preventing it from entering.

The large ends of the carbon d, which are below, are placed upon the column h, and are provided with metal hooks e, which are split and separated when the links or connections o are put in their places, to cause the current to pass, and to communicate it to the conductor g' in such manner that the carbons are not insulated as long as the large ends of the carbons above, bearing the screwed metal pin p', which enter in the insulating-plate c, do not touch one another, and it is only the first carbon intended to burn which is in communication with the conductor g by the aid of a hook, e, and the connection o. This first carbon carries a washer or perforated disk, q, screwed on the upper part of the pin p, but only descending to the plate c.

The second carbon upon the pin p carries a washer, q, upon which is placed a plate, r, having two holes, the one large, r^1, and the other small, r^2, and retained by a nut, b. r^2 is bound between the washer and the screw, while r^1 allows the pin p of the first carbon to pass through without touching it. If the first carbon breaks, the large end of the carbon e will descend and bring down the
4084 ring q upon the piece r, which will establish a current between the first and the second carbon, and so on throughout. We place liquid in the bowl j, in such manner as to slightly cover the lower edge of the globe k. I employ, by preference, olive-oil, because it disengages no vapors when at a certain degree of temperature.

I claim—

1. The carbon electrodes provided with insulated supports independent of the metallic conductor, substantially as herein described.

2. The combination of the carbon-pins f, having the enlarged ends d, with the metal conductors e, inserted into the said enlarged ends of the carbons, substantially as shown and described, for the object specified.

3. The combination of the carbon-pins f, having the enlarged ends d, the wires e, and the links o, flexibly connecting said wires and the principal conductors, as herein shown and described.

4. The supporting column h, arranged within and filling a portion of the globe or cover k, substantially as and for the purpose herein specified.

5. The combination of the globe k, the column h, and the valve n, surrounding said column between it and the globe, and constructed to permit the escape of the dilated air from the globe, and prevent the entrance of the external air, substantially as shown and described.

6. The combination of the thin sticks of carbon f, their enlarged ends d, the wires e, inserted in said enlarged ends, the flexible con-

nections *o*, the insulating plate *c*, the plates *r*, screw-pins *p*, washers *q*, and nuts *b*, substantially as and for the purpose described.

7. The combination, with the series of carbon electrodes, and a flexible connection communicating with the electric conductors, and constructed to automatically pass the electric current from one carbon electrode to the other in case of the breakage of either, as set forth.

4086 UNITED STATES PATENT OFFICE.

HENRY WOODWARD, of Toronto, Ontario, Canada, assignor, by mesne assignments, to Rupert Mearse Wells, Thomas Richard Fuller, and Ernest Heimrod, of same place, and Charles H. Woodward, of Lindsay, Canada.

Improvement in Electric Lights.

Specification forming part of Letters Patent No. 181,613, dated August 29, 1876; application filed January 4, 1875.

To all whom it may corncern:

Be it known that I, Henry Woodward, of the city of Toronto, county of York, in the province of Ontario, Canada, have invented new and useful improvements in the art or process of obtaining artificial light by means of electricity; and I do hereby declare that the following, taken in connection with the drawings which accompany and form part of this specification, is a description of my invention sufficient to enable those skilled in the art to practice it.

In the first place, I use a gas-engine or other suitable motive power, for the purpose of rotating a magneto-electric machine, and at such a velocity as shall create electricity sufficient to heat certain pieces of carbon hereinafter described. The magneto-electric machine should be of sufficient power for the purpose of heating the carbon to a state of incandescence. A piece of carbon of suitable size is scraped and shaped until fitted for the purpose; one pole is then attached to the top of the carbon, and the other to the bottom thereof, by suitable electrodes. It is then inclosed in a globe or other vessel, either of glass or other suitable material. The air is then exhausted from the said globe or vessel after it has been hermetically sealed at the ends, and the globe is then filled with a rarefied gas that will not unite chemically with the carbon when hot. Electricity is now supplied, and in sufficient quantity to heat the carbon within the vessel to a state of incandescence. The rarefied gas previously introduced now becomes luminous, and constitutes the light herein designated as "Woodward's electric light."

This arrangement and process will give a light of any required intensity, and there is, practically, no limit to the number of lights that may be obtained from one magneto electric machine.

In the accompanying drawings, the same letters of reference indicate the same parts in all the views, and also in this specification.

(Here follows diagram marked p. 4085.)

Figure 1 is an elevation or front view of a piece of carbon, and is marked B. It is supposed to be scraped and shaped until suitable for the required purpose.

Fig. 2 is also an elevation or front view of a piece of carbon with the electrodes E E attached thereto, leading to and from the positive and negative poles of the battery, one being attached at the top and the other at the bottom of the carbon.

Fig. 3 is a sectional elevation, showing a globe marked A, but which may be a vessel of any other suitable form. The prepared carbon B is also shown therein, with the aforesaid electrodes E E attached thereto; showing, also, a tube, C, with an air-tight stopcock, to be used in exhausting the air from the globe A, and for the injection of rarefied gas into the same; showing, also, the hermetical sealing of said vessel at the ends G G of the tubes, and showing, also, the stand D.

Fig. 4 is a sectional elevation, showing the adaptation of another form of vessel, A. This drawing is on a larger scale, in order to show the manner of closing the ends of the vessel, which is done by brass sockets, that at the top being marked K, and that at the bottom being marked L; showing, also, a carbon, B, different in form from that in the other vessel, and having the two electrodes E E running to and from the poles N and M.

Fig. 5 is an elevation, showing one mode of connecting the various lights with the machine by means of two trunk-wires or electrodes, H H, running from the positive and negative poles M and N of the machine, with branches *b b*, &c., therefrom, to each light.

Fig. 6 is also an elevation, showing another method of connecting the lights with the machine, each light having a distinct
4087 wire, *b*, running to each pole M N of the machine or battery.

Having thus described my invention, I claim—

A carbon, B, in combination with a lamp or other suitable vessel, A, filled with rarefied gas, possessing the property of not chemically combining with the carbon when in a state of incandescence, in connection with the described arrangement and mode of connection of the electrodes E E with the carbon, all as shown and set forth.

HENRY WOODWARD.

United States Patent Office.

William E. Sawyer, of New York, and Albon Man, of Brooklyn, N. Y.

Improvement in Electric Lamps.

Specification forming part of Letters Patent No. 205,144, dated June 18, 1878; application filed May 16, 1878.

To all whom it may concern:

Be it known that we, William Edward Sawyer, of the city, county, and State of New York, and Albon Man, of the city of Brooklyn, county of Kings, State of New York, have invented certain new and useful improvements in electric lamps, of which the following is a full, clear, and exact description.

At the present day it is not new to produce a light by causing the electric current to heat a carbon conductor to incandescence in a vacuum, or in nitrogen, or in other gas; but no lamp has yet been devised which would be practically operative, and for these reasons: First, the methods that have been employed for charging the lamp with the artificial atmosphere—such as the displacement of mercury, water, or air by the gas, or the combustion of phosphorus in the lamp—are imperfect; a perfect vacuum is unattainable; some oxygen or other element or compound remains in the lamp, and slow consumption or disintegration takes place, for the remanent gas or vapor other than nitrogen or hydrogen attacks the carbon, oxygen forming with it carbonic acid or oxide, which in turn is decomposed, with the result of depositing the carbon upon the globe and setting free the oxygen to attack fresh carbon; second, it has been found practically impossible, under the varying degrees of heat and pressure, to maintain perfect joints, and the result is that expansion of the artificial atmosphere by the heat from the luminous conductor expels a portion of the same, and the contraction of the atmosphere upon cooling causes a portion of the external air to penetrate the globe, thus supplying oxygen which at the next lighting feeds upon the carbon; third, the unequal expansion of the carbon and its holders has resulted in fractures of the former, so that however perfect the atmosphere in the globe the lamp has never been permanent.

To obviate these several difficulties is the object of our invention.

To charge our lamp we prefer the employment of nitrogen gas, and this we produce in the lamp by our improved process in a state of great purity. As a safeguard against an infinitesimal leakage we prefer to place in our lamps a small quantity of sodium, potassium, or other agent having a great affinity for oxygen, whose oxidation, unlike the oxidation of phosphorus, produces no vapor, but a solid not easily changed by heat. As an additional safeguard we prefer to place in our lamps a quantity of freshly-burned lime, so that any traces of carbonic-acid gas which might suffer the decomposition and depositing hereinbefore mentioned may be quickly absorbed and rendered harmless. To make our lamp perfectly air-tight we have recourse to certain fittings to the opening at the base of the globe, which will be described in detail hereafter. To guard against great heating and unequal expansions at the joints, which would emperil the sealing of the lamp and soon render it useless, we isolate the incandescent carbon from the lower part of the globe, where the joints are situated, by a disk or diaphragm of some refractory substance—preferably soapstone or porcelain—whereby we prevent all downward radiation of the heat and keep the joints comparatively cool at the same time that the upper part of the globe may be very hot. Furthermore, to prevent conduction of the heat from the incandescent carbon to the joints by the metallic connections communicating therewith, we arrange the two conductors leading upward from the base in a spiral, volute, or fluting form, so that we obtain considerable length of conductor in a limited space, and very little of the heat reaches the base. By means of the several devices shown and described we have succeeded in obtaining a permanently airtight lamp. Our arrangement for avoiding fracture of the carbon will be fully described hereinafter.

(Here follow diagrams marked pp. 4088 & 4089.)

In the drawings accompanying and forming a part of this specification, figure 1 is a side view and Fig. 3 a partial front view of the lamp. Figs. 2, 6, and 7 are views of parts thereof. In Figs. 4, 5, and 8 we have indicated possible modifications of the lamp; and in Fig. 9 is shown the general arrangement of apparatus for charging the lamp with the artificial atmosphere in which the carbon is preserved.

4091 Referring to Figs. 1 and 3, A is the glass globe provided with a rim or flange, A′, (better shown in Fig. 6,) by means of which it is clamped to the glass base or stopper B. (Better shown in Fig. 7.)

We have shown the globe in the form of a tube closed at one end; but it is clear that its shape may greatly differ from that shown. The glass may be "diamond-cut" to effect diffusion of the light, or translucent to soften it; or the globe may be surrounded by a second globe possessing these characteristics, and a second globe would, in fact, be necessary in a lamp placed out-of-doors or subject to wetting, as the heated globe A, if unprotected, would be in great danger of breakage.

To the base of the globe is ground the glass stopper B (better shown in Fig. 7) with great nicety, in order that the fit may be perfect.

Slipping over the top of the globe A is a brass flange, L, shown partially cut away, which bears upon the rim A,′ to bring the globe firmly down upon the stopper B, the pressure upon the rim of the globe being softened and equalized by the cushioned-flange of wood, paper, or other yielding substance, P.

Under the stopper B is placed, first, a flange of wood or other

yielding substance, M; second, a flange of spring-rubber, M; and, last, a flange of brass, O, all shown partially cut away. Through all these flanges and the flange L go the bolts *j j*, of which there may be any desired number, so distributed around the circle as to equalize the pressure upon the rim A′ and stopper B. The bolts *j j* are secured in the usual manner by nuts *k k*. The flange P softens the pressure upon the rim of the globe A′, preventing fracture. The brass flange L yields to any inequalities which may exist. The wooden flange M softens the pressure upon the stopper B, preventing fracture thereof, while it is unaffected by any heat that may there exist; and the rubber flange N, protected from heat, acts as a spring to yield to slight unequal expansions and maintain a perfect contact between A′ and B. The rubber flange may, however, be omitted, and the form of the stopper B may be changed to that of a stopper ground into the end of the globe A, as stoppers are ground into bottles.

In setting up the lamp, we slightly coat the lower ground edge of the rim A′ with fir-balsam, or some cement, in order the better to insure that hermetical sealing which is indispensable to the preservation of the incandescent conductor.

Through the stopper B are drilled two holes, Fig. 7, through which pass the bolts Q Q, protected or not by a cloth or paper lining. These bolts are tubes, and their function is of the greatest importance. The bolt-heads are accurately fitted to the upper surface of the stopper, and under them, coated with balsam or some cement, are thin paper or tin-foil washers *l l*. The nuts *m m* are accurately fitted to the under surface of the stopper, and under them are similar washers *l l*, similarly prepared. Thus arranged, the bolts are permanently fixed to the base, and when the lamp is charged with the artificial atmosphere required the binding-posts *n n*, whose set-screws are *o o*, similarly guarded by washers *l l*, are set up upon the bolts' ends, whereby the lamp is hermetically sealed.

Entering the bolt-heads Q Q, so as to form a perfect connection with them, are two tubes, J K, arranged fluting, volutely, or spirally, as desired, the tube K being closed at the top, but provided with an opening, *i*, and the tube J being continuous, so that communication with the top of the lamp, when the binding posts *n n* are removed, is by way of the tube J, and to the base of the lamp by tube K at the point *i*. The object of this arrangement will hereinafter be made apparent.

C is a disk, of soapstone, porcelain, or other refractory substance, not readily fractured by heat, which almost entirely fills the globe A at or near the middle thereof. This, like the glass stopper B, is perforated with two holes, through which pass the metal tube H and the metal rod I, both of which are provided with a screw-thread at their lower ends. The tube H and the rod I are firmly fixed to the disk by means of nuts *f f f f*, as will be comprehended without further explanation. Into the lower ends of H and I, and firmly fixed thereto in any manner whatsoever, enter the conducting-tubes J and K. Let into the rod I is a short stick of carbon, D, rounded at the top, which we prefer to fasten to the rod by winding around the two the naked wire *h*, which may be of copper, silver, or platina.

Sliding up and down in the tube H is a rod, F, bent at right angles at the top, so as to bring the extremity on a line above the carbon D. The rod F is prevented from turning in the tube H by the pin *d*, fixed to the rod, and working in the slot *e*.

The light is produced by the heating of the small carbon rod E at the point E′, between the clamp G and the top of carbon D, connection with the small carbon E being had both through clamp G and the platina piece *a* on bent rod F. The rod F exerts a pressure upon the carbon E, which continues the same without regard to the length of the carbon, and thus, should fracture or a slight consumption of the carbon occur at the first lighting or any subsequent lighting of the lamp, the necessity of taking down the same, renewing the carbon, and recharging the globe, is obviated, inasmuch as the weight of the rod F gently forces the carbon through the clamp G until a new contact between E and D is established. The construction of the clamp G is shown in Fig. 2, which is a top view of the same. It consists of a copper or silver strip bent around the tube H and fixed to the same either by a pin or by its own pressure. At the end of the clamp are pinned two pieces of platina or iridium, *b b*, which may or may not touch each other, but each of which is slightly grooved to form an opening, *c*, through which the carbon rod E may pass, 4092 and in which it may be held in place. The copper or silver strip which constitutes the main portion of the clamp, serves the purpose, through its expansibility, of increasing and lessening the distance between the platina pieces *b b* according to the degree of heat experienced, thereby in great measure avoiding fracture of the carbon at E′ when intensely heated by the current.

In setting up the lamp we prefer to place inside the globe a lump of sodium or potassium, R, and one or more lumps of freshly-burned lime, S, although we do not confine ourselves to the introduction of these substances. Sodium and potassium being conductors of electricity may be protected from the conductors to the carbon, if deemed necessary, by inclosing the same in a bag of cloth, or in a glass tube open at one end.

We are aware that phosphorus has been placed in sealed lamps to remove the oxygen by its slow combustion; but the phosphorus acid evolved is not only fatal to the carbon when intensely heated, but beclouds the globe and obscures the light. Neither sodium nor potassium exerts any such deleterious influence, the product of oxidation being a solid, incapable, under the circumstances, of yielding either gas or vapor of any kind; hence the use of such by us as a safeguard in the lamp. Should carbonic-acid gas exist or at any time be evolved in the lamp it is quickly taken up by the lime, or by the soda or potassa formed by oxidation of the sodium of potassium.

In Figs. 4 and 5 we have indicated a modification of our lamp to the chandelier form.

We may arrange any number of carbons, D and E, around a circle in the form shown in Figs. 1 and 2, having for each a feeding device, F G, the whole being in a single globe, or we may arrange the chandelier as shown in Fig. 4, U being a metal disk provided with five or more or less tubes, U′, in which slide the small carbon rods E E, which are forced into contact with the lower carbons, D D, by the downward pressure of rods T′, surmounted by the weights T T. All of the lower carbons, D, connect with the disk V, to which is fixed tube V′, and through this tube and the disk, but insulated therefrom, passes the conductor W, which is attached to the upper disk, U, and is therefore in connection with all the small carbons E.

In Fig. 8 we have indicated a modification of the single-carbon lamp, the clamp G being dispensed with and the bent rod F being provided, like the rod I of Fig. 1, with a carbon piece, X, wired to it precisely as carbon D is wired to rod I. The lamp being set up the next important thing is to charge it with the atmosphere, which will prevent consumption of the carbon, and we will now proceed to describe in detail our improved process for so charging the lamp.

The various methods of manufacturing nitrogen gas are well known.

Having dried and purified the gas until it stands all tests we pass it into a dry receiver, preferably a bag of vulcanized rubber. Referring, now, to Fig. 9: Into a glass tube, *p p*, in a furnace, Z, by means of which the tube may be heated to any desired extent, we place a quantity of sodium, or potassium, or other agent having a great affinity for oxygen, whose oxidation produces a solid. If deemed advisable we may add to the same a purifying agent or agents. Heat, while not essential, greatly facilitates the operation, and therefore, even with potassium, we prefer to employ the furnace. To one end of the glass tube *p p* by means of a flexible tube, *r*, we attach the receiver Y, filled with nitrogen, and having removed the binding-posts *n n*, Fig. 1, from the lamp, we connect the other end of the tube *p* by means of a flexible tube, *r*, and nipple *s* with the bolt Q, which connects with tube J leading up to the top of the lamp. We then by means of weight *q* force a sufficient quantity of the nitrogen through the tube *p* and the lamp to greatly dilute and mostly displace the atmospheric air contained therein. The empty closed receiver Y′ we then attach by a flexible tube, *r*, and nipple *s* to the bolt Q, which is connected to conductor K of the lamp, and the lamp now being in a closed circuit of nitrogen gas the operation of purification begins. The gas passes slowly from receiver Y through the tube *p;* thence through the tube J to the top of the lamp at the point *u*, and thence down and outward at the point *t* into the receiver Y′, and from Y′ by the reverse action it is repassed into receiver Y. This transference is repeated until there is no further evidence of oxidation, when, the receiver Y′ being empty, a pressure is exerted upon the receiver Y and maintained so as to cause a slight escape of gas from the lamp during the time that Y′ is disconnected, and the binding-post being put onto the bolt Q connecting with conductor K. The nipple *s* is lastly disconnected from the bolt Q of tube J, and the binding-post for that tube put on, when the lamp is ready for use and will remain so for an indefinite period, the line S in the lamp absorbing any traces of carbonic-acid gas that may be present or evolved, and the sodium or potassium burning out any traces of oxygen that may enter during the closing of the tube J.

By the process described the lamp may be charged with absolutely pure nitrogen gas, and it is clear that any number of lamps may be placed in the circuit and simultaneously charged, the gas in transference passing seriatim through the lamps.

Having thus fully described our invention, what we claim as such and desire to secure by letters patent is—

1. An electric lamp in which the globe and stopper, both of glass or other vitreous substance, are ground together and held together by a clamping device.

4093 2. In an electric lamp, the combination, with suitable conductors of electricity, of an inclosing-globe provided with a rim or flange, A′, forming an integral part of such globe, as an for the purpose specified.

3. The combination of the vitreous globe A of an electric lamp and the cushion P, placed, as shown and described, above the vitreous flange thereof, for the purpose of supporting a clamping device.

4. The combination of the vitreous globe A of an electric lamp and the cushion N, placed, as shown and described, under the stopper thereof, for the purpose of supporting a clamping device.

5. The combination of the globe of an electric lamp and the two cushions N and P, placed, as shown and described, for the purpose of supporting a clamping device.

6. In an electric lamp, a tube bolt, Q, and binding-post *n*, in combination with a packing, *l*, under said binding-post.

7. In an electric lamp, a tube-bolt, Q, nut *m*, binding-post *n*, and packings *l l l*.

8. The combination of the clamp G and the cross-piece *g*, as and for the purpose specified.

9. In an electric lamp, a tube leading from an external connection to or near to the top of the globe, and having an opening thereat, in combination with an opening at or near to the base of the globe, for the purpose of facilitating the filling of the globe with a carbon-preservative atmosphere, substantially as shown and described.

10. In an electric lamp, two unobstructed tubes leading from external connections into the globe thereof, and so arranged as to facilitate the charging of the globe with a carbon-preservative atmosphere.

11. In an electric lamp, a diaphragm obstructive of radiant heat interposed between the luminous part or parts of such lamp, and the air-tight joint or joints thereof, as and for the purpose specified.

12. An electric lamp within which the conductors leading from the air-tight joint or joints thereof to the luminous part or parts thereof are so formed, lengthened, or broadened as to have great radiating surface, so that conduction of heat from such part or parts to such joint or joints is in great measure, if not wholly, prevented.

13. In an electric lamp, the long coiled conductor J, opening at its upper end, and connecting with one electrode of such lamp.

14. In an electric lamp, the long coiled conductor K, opening at the base of such lamp, and connecting with one electrode thereof.

15. In an electric lamp, an absorbent of carbonic-acid gas.

16. In the sealed globe of an electric lamp, containing an azotic or other carbon-preservative atmosphere, an absorbent of carbonic-acid gas.

17. In an electric lamp, an agent having a great affinity for oxygen whose oxidization produces a solid unalterable by the natural heat in the lamp, such as sodium or potassium.

18. The combination, in an electric lamp, of an absorbent of carbonic-acid gas and an agent having a great affinity for oxygen whose oxidization produces a solid unalterable by the natural heat in the lamp, such as sodium or potassium.

19. A carbon rod, piece, or pencil heated to incandescence in an atmosphere deprived of oxygen, in which atmosphere is permanently an oxidizing agent whose oxidization produces a solid, which agent may be sodium or potassium, or other readily oxidizable metal.

20. A carbon rod, piece, or pencil heated to incandescence in an atmosphere deprived of oxygen, in which atmosphere is permanently an absorbent of carbonic-acid gas.

21. A carbon rod, piece, or pencil heated to incandescence in an atmosphere deprived of oxygen, in which atmosphere is permanently an oxidizing agent, such as sodium, potassium, or other readily oxidizable metal, in combination with an absorbent of carbonic-acid gas.

22. A sealed electric lamp inclosing an agent or agents for purifying the atmosphere contained therein from oxygen or oxygenic gases.

23. The herein-described method of charging an electric lamp with a carbon-preservative atmosphere, consisting in placing the lamp in the circuit of a purifying agent or agents and two gas-receivers, one of which is primarily preferably filled with the carbon-preservative gas and the other empty, and forcing the gas back and forth from one receiver to the other, each time through the lamp and the purifying agent or agents, until the atmosphere becomes pure or nearly so.

24. The herein-described method of charging an electric lamp

with a carbon-preservative atmosphere, consisting in placing the lamp in the circuit of a purifying agent or agents and two receivers, one of which is primarily preferably filled with a gaseous medium and the other empty, and forcing the gaseous medium back and forth from one receiver to the other, each time through the lamp and the purifying agent or agents, until the atmosphere in the lamp becomes pure, or nearly so.

25. The method of charging an electric lamp with a carbon-preservative gas by intermittently passing a purified atmosphere, or an atmosphere undergoing purification, into the globe thereof, and thereby successively diluting and purifying the contents thereof, until finally all or nearly all the oxygen is removed therefrom.

UNITED STATES PATENT OFFICE.

WILLIAM E. SAWYER, of New York, and ALBON MAN, of Brooklyn, N. Y.

Electric-lighting System.

Specification forming part of Letters Patent No. 205,303, dated June 25, 1878; application filed May 31, 1878.

To all whom it may concern:

Be it known that we, William Edward Sawyer, of the city, county, and State of New York, and Albon Man, of the city of Brooklyn, county of Kings, and State of New York, have jointly invented certain new and useful improvements in electric-lighting systems, of which the following is a full, clear, and exact description.

In another application filed by us we have shown and described an electric lamp in which light is produced without consumption of the carbon producing it.

The object of our present invention is to provide for such a distribution and application of the electric current as will render our own or any other lamp practically operative upon an extensive scale.

Our system consists in (first) a new arrangement of electrical circuits, which are in part (second) composed of conductors diminishing in transverse mass as they increase in length, and in part (third) of conductors having great radiating-surface, provided with (fourth) safety-switches to guard against the dangers of short-circuiting in connection with (fifth) lamps and lamp-lighting devices, by means of which the lamps are lighted and extinguished without danger of fracturing the carbons thereof, or of interrupting or changing the resistances of the circuits.

(Here follow diagrams marked pp. 4094 & 4095.)

In the drawings accompanying and forming a part of this specification, figure 1 is a general view of the arrangements at each lamp, including a top view of the lamp-lighter and a side view of the safety-switch. Figs. 2 and 3 are other views of parts of Fig. 1, and in Fig. 4 is outlined a modification which may be made of a part of the lamp-lighter. Fig. 5 is a diagram of the circuits, showing the combination of several of the sets of apparatus shown in Fig. 1.

Referring, first, for convenience of description to Fig. 5, *j* is a generator of electricity supplying the outletting conduits or conductors *k k*, which branch into conductors *l l m m*, the continuations of which are shown only in the case of conductors *m m*, the circuits of conductors *l l* being merely indicated by the + and — signs. There may be any number of branches *l l m m* leading from the outletting conduits according to the volume of current supplied by the generator *j*. The outletting conduits *k k*, as indicated by the thickness of the lines, are large, in order, without heating and consequent waste, to conduct the great quantity of current supplied. It is clear that all the conductors may be of uniform size; but the expense of such, as against conductors diminishing in transverse mass as they extend outward, is so considerable that we have adopted the latter plan. Therefore we make the first sections, *m m*, of the circuits smaller than the outletting-conduits, and the next sections, *o o*, still smaller, and so on indefinitely. In the cross-branches *n* and *p* in circuits *q q*, derived by means of resistances R R, we place the electric-lighting apparatus of our invention, Q′.

Referring now to Figs. 1, 2, and 3, Q is the lamp; A D M, the lamp-lighter; U V X, the safety-switch, and R the resistance. (Shown in Fig. 5.)

In the lamp of our invention hereinbefore mentioned, which we prefer in all cases to employ, a small piece of carbon is heated to incandescence in an atmosphere with which it will not chemically combine. Other attempts to produce such a lamp have been made, but among other things it has been found almost impossible to prevent fracture of the carbon. The fracturing of the carbon is mainly due to sudden changes in temperatures. While it becomes soft and pliable under the heat of the current at ordinary temperatures, it is extremely brittle, and instantaneous heating from its normal condition to a temperature of from 5,000° to 40,000° Fahrenheit tends to disrupt the particles and establish the voltaic arc by which in a moment the carbon is destroyed. The lamp-lighter avoids this difficulty. Again, an accidental short circuit may occur with the result of supplying so much current to the lamp as to volatilize or destroy the carbon unless instantly and automatically checked, and this danger is provided against by the safety-switch. To avoid undue electrical heating from accidental or other causes in the conductors, and the great resistance occasioned by the heating of a
conductor, especially when in the form of a rheostat, we con-
4097 struct our artificial circuits, rheostats, or resistances R, of flat
or ribbon wire, in order that they may present considerable radiating surface, and thereby keep cool when otherwise they might be melted by the electric heat.

The connectors Z Z of Fig. 1 indicate the points at which the lighting-circuits leave the branches *n* and *p* of Fig. 5.

A is a flat metallic spring-lever fixed to holder B by screw C, and making connections, when the lamp Q is not in circuit, with contact-point J.

D is a lever provided with finger-piece D^2, working on screw or stud E. When the lever D is in the position shown, its rounded extremity D′ is clear of spring-lever A; but when moved to the left the end D′ makes connection with the spring-lever and simultaneously lifts the latter from its connection with contact-point J.

Fixed to the lever D is a mutilated spur-wheel F, the teeth E′ of which mesh into the pins G′ of pinion G. The pinion G, rotating on screw or stud G^2, carries with it a fan, H, situated below the pinion; but as the construction of such mechanism is thoroughly understood, we have not deemed it necessary to illustrate the same in detail. The object of the fan is to retard the movements of the lever D, and thus compel the person lighting a lamp to "turn on" the current gradually. Any other means of insuring a gradual movement of the mechanism will answer the purpose; and, as an example, we have indicated in Fig. 4 a modification that may be made in this apparatus, *a* being a tube of glass or metal, in which travels a plunger, *b*, on piston-rod *c*, provided with finger-hook *d*. The piston-rod works loosely in the tube-head *f*, and the plunger is pressed toward tube-head *e* by coiled spring *i*. In the head *e* is an opening, *g*, provided with a valve, *h*. This device may be attached to the apparatus of Fig. 1, so that, for instance, when the plunger is drawn into the position shown, a catch shall take hold of the lever D, and the piston-rod being released and the valve *h* closing, the slow escape of the air as the plunger is followed up by spring *i* may cause the piston-rod to slowly move the lever D and light the lamp. The piston-rod *c* disengaging when the lamp is lighted, all that is necessary in order to put out the light is to move the lever D back to the position it occupies in Fig. 1, and this may be arranged to be accomplished by a second catch upon the piston-rod *c*, and the same movement of the rod as that which takes place upon lighting the lamp; but since, as before observed, any retarding device will answer the purpose, we have not deemed it necessary to enter into the details of modifications, which would only needlessly cumber our specification.

Recurring to Fig. 1, K and L are resistances of, say, fifteen ohms each. P is a resistance of, say, twenty ohms; and O O are five resistances of, say, two ohms each. N and N′ are stops for lever D. M M are six metallic contact-pieces, with which lever D makes connection as it is moved, which contact-pieces are connected, as shown with the five resistances O O. All of these resistances may be of the character of resistances R, which, as better shown in Fig. 2, is a flat wire or ribbon of metal. This ribbon is wound over pins T, fixed to any suitable insulating-base. The connectors R R′ may be of any desired form. Being in the shape of a ribbon, the conductor constituting the resistance has a large radiating-surface, and a space being left between each layer to permit of free access of air any heat which may be evolved is rapidly dissipated. The resistance R operates to divert a portion of the current flowing in the branches into the lamp Q. In many cases it may be omitted.

The safety-switch is of the simplest construction. U is an ordinary electro-magnet; V, an ordinary armature-lever; W, a standard, in which the armature-lever is pivoted, and V^2 a retractile spring. The pin V′, fixed to the lever V when the lever is not actuated by the magnet U, serves to hold the bent lever X, working in its bearing X′, in the position shown in the drawings. When, however, the lever V is attracted by magnet U, the pin V′ is lifted and the lever X, actuated by spring Y, escapes from its imprisonment.

The operation of the switch is as follows: When the proper strength of current is supplied to the lighting-circuit, the spring V^2 is so adjusted that the lever V does not respond to magnet U; but when from any cause there is an increase in the current which might injure the lamp or other apparatus or other lamps in circuit, the retractile force of the spring V^2 is overcome by the attractive force of the magnet, and the circuit through spring Y, lever X, armature-lever V, standard W, and the magnet is instantly broken by the release of lever X.

In the place of the safety-switch we may interpose in the circuit a section of a conductor more readily fused than the conductors constituting the rest of the circuit, so that when there is too much current this section shall be instantly melted and the continuity of the circuit destroyed.

The operation of our apparatus is as follows: The current enters the resistance R from the points Z Z. From the resistance at the points R′ and R^2 the current divides, the required portion entering the lighting-circuit. When the lever D is in the position shown, the current passes from the point R^2 to the spring-lever A, contact-point J, resistance L of fifteen ohms, and thence through spring Y, levers X and V, standard W, and magnet U to the point R′. In this position of the lever D the lamp is not in operation, and the resistance of the circuit is fifteen ohms, (disregarding everything excepting resistance L.) To light the lamp, the lever D is moved
to the left, and while it is still in connection with the first
4098 contract-point, M, its end D′ makes connection with spring-
lever A, and the connection between A and J is broken.
Without having been interrupted the circuit of the lighting apparatus is now divided into two sub-circuits, one of which is from the point R^2 by way of spring-lever A, resistance K, of fifteen ohms, resistance L, of fifteen ohms, and the safety-switch, to point R; total resistance of the sub-circuit thirty ohms. The other sub-circuit is from the point R^2 by way of spring-lever A, lever D, the first contact-point M, the five resistances O O, of two ohms each, the lamp Q, resistance P, of twenty ohms, and the safety-switch to point R; total resistance thirty ohms the resistance of the lamp while the carbon is cool being practically *nil.* The lighting-circuit being now divided into two sub-circuits of thirty ohms resistance each, the resistance of the circuit is still fifteen ohms, and although the lamp has been introduced, no disturbing influence has been exerted upon other lamps or circuits. The current flowing through the lamp begins to heat the carbon, which rapidly acquires resistance, and the resistance of the carbon increases in proportion to the movement of the lever D over the contact-points M until all of the five resistances O, of two ohms each, have been cut out of circuit, and the lamp is left in circuit with the resistance P, of twenty ohms; but the resistance of the lamp is now ten ohms, so that the total resistance of the sub-circuit of the lamp is still thirty ohms, and, the resistance of the other sub-circuit remaining unchanged, the joint resistance is as at the outset fifteen ohms.

It will thus be seen that the lamp-lighter of our invention not only prevents the too sudden heating of the carbon, but completely obviates the disturbing influences of changes in resistance which have heretofore accompanied the lighting or extinguishing of a lamp.

The application of the lamp-lighter to electric lamps in which the light is produced by the voltaic arc by removing resistances from the circuit in proportion as the carbons separate will be comprehended without further explanation.

Recurring now to Fig. 5, in which we have shown more than one branch from a single source of electricity, and more than one lamp in each branch, we are aware that it is not new to place a number of lamps in series in the circuit of a generator. or to divide the current among several conductors, each containing a single lamp, or to divide the current among several cross-branches, *n p*, each containing a single lamp. It is new, with us, however, to divide the current among several conductors, or several cross-branches, each containing two or more lamps, and lest the advantages of our arrangement may not be apparent we will proceed to explain the same in detail.

It is well understood, first, that to produce a good electric light a current of electricity combining considerable intensity is indispensable; second, in dividing the electric current among a large number of lamps, if there is a conductor from the generator to each lamp, or a cross-branch to each lamp, the quantity of current supplied must be very great, and in the event of a short circuit occurring in any lamp the result would be disastrous to the lamp, if it would not extinguish all the other lamps; third, in placing a large number of lamps in series, each lamp having a considerable resistance, the intensity of the current, in order to overcome the combined resistances, must be very great, and to obtain the proper current is far more expensive than it is to obtain a current of greater quantity with less intensity.

To illustrate the disadvantages attending the placing of very many lamps in series, let it be assumed that there are one hundred lamps in circuit, and that the resistance of each lamp is ten ohms, then the combined resistance of all the lamps is one thousand ohms, and this in the service of current for electric lighting is impractical. Suppose, now, that there are one hundred conductors leading from the generator, and that in each conductor there is a single lamp of ten ohms resistance, then the joint resistance of the one hundred lamps is the tenth of an ohm. Not to mention the wear and tear upon the generator of so slight a resistance, let it be supposed that a short circuit occurs in one of the lamps—as, for instance, by an accidental connection across the terminals of the resistances K, L, and P, thus cutting out those resistances—then the resistance of its conductor becomes *nil*, and not only are all the other lamps deprived of the current, or the greater portion thereof, but the short-circuiting lamp circuit receives so much current that the lamp is destroyed, even should there be no other disastrous result. If to avoid this we increase the resistance of the conductors, artificially or otherwise, outside of the lamps, we simply waste current in overcoming the added or artificial resistances which clearly would be costly, and consequently impractical. Adopting, finally, our plan, let it be supposed that there are ten conductors or cross-branches, *n p*, leading from the generator, each containing ten lamps of ten ohms resistance each. The combined and joint resistance of the circuit of the generator is ten ohms: —$\frac{10 \times 10}{10} = 10$. The resistance of the circuit is better suited to the generator, and should a lamp short-circuit the result would not be disastrous. On the contrary, it could hardly be detected. The very slight proportion of current taken from the ninety lamps in the nine perfect conductors, and the very slight proportion of current added to the nine lamps in the conductor containing the short-circuiting lamp would have no appreciable effect upon either the ninety or nine.

In concluding the description of the system of our invention we remark, first, that there may be in each lamp-lighter any number
of resistances O, of any number of ohms, or parts of an ohm,
4099 resistance each; second, that the lever D may further operate
to cut out resistances K and L, and, finally, to break their circuit altogether, reducing, while doing so, the resistance of the circuit of lamp Q; third, that everything in the lamp-lighter, excepting the *the* lever D, resistances O O, and lamp Q, may be omitted, since the resistances O O may be *be* increased to such an extent that when they are all in circuit the current will be too weak to heat the carbon, and removing them from the circuit will add resistance to the carbon by its heating in proportion as they are removed.

Having thus fully described our invention, what we claim as new, and desire to secure by letters patent, is—

1. The combination, with an electric lamp, of a switch, which in lighting the lamp gradually removes a resistance for the circuit thereof.

2. The combination, with an electric lamp, of a switch, which, while preserving the continuity of the circuit, gradually removes a resistance from the circuit of the lamp.

3. The combination, with an electric lamp, of a resistance in the circuit thereof which is lessened as the resistance of the lamp is increased.

4. The herein-descri-ed method of lighting an electric lamp, consisting in causing the flow of current in such lamp to increase in strength slowly.

5. In an electric-lighting system, two or more conductors supplied with electricity by the generator of electricity which is the common source of supply for such system, and in each of these conductors, or in circuits derived therefrom, two or more electric lamps, the same being so arranged for the purpose of insuring the necessary distribution and subdivision of the current without artificial lengthening of the circuits by the introduction of resistances which would only waste the current, as set forth.

6. In an electric-lighting system, rheostats, resistances, &c., having great radiating-surfaces, the same being preferably constructed of a thin flat conducting medium, to which the air is given free ac-

cess, so that the heat generated by the current is rapidly radiated or conducted off.

7. In an electric-lighting system, an electrial apparatus energized by the current flowing in such system, which, when there is an abnormal flow of current in a part or parts of such system, automatically operates to disrupt, disconnect, or change the circuit of such part or parts.

UNITED STATES PATENT OFFICE.

WILLIAM E. SAWYER, of New York, and ALBON MAN, of Brooklyn, N. Y.

Electric Lamps.

Specification forming part of Letters Patent No. 210,809, dated December 10, 1878; application filed November 5, 1878.

To all whom it may concern :

Be it known that we, William Edward Sawyer, of the city, county, and State of New York, and Albon Man, of the city of Brooklyn, county of Kings, State of New York, have invented certain new and useful improvements in electric lamps, of which the following is a full, clear, and exact description.

In letters patent of the United States No. 205,144, dated June 18, 1878, granted to us, we have shown and described an electric lamp differing not essentially, in so far as its main features are concerned, from that of our present invention, the object of which is to produce a lamp more tasteful in appearance and better adapted to afford a successful electric light

(Here follows diagram marked p. 4100.)

Referring to the drawings accompanying and forming a part of this specification, figure 1 is a sectional view of the lamp, and Fig. 2 a cross-section of a part thereof. In Figs. 3 and 4 we have indicated modifications which may be made in the form of the internal conductors.

A is a glass globe, provided with a flange, B, substantially as shown and described in the letters patent referred to.

C is the stopper; *a a* are the tubular bolts passing through the same, and *f* and G are cushions to soften the pressure upon the glass flange and stopper of the two metal flanges D and F, drawn together by bolts *e e*, the whole of which has been fully described and claimed in the above-mentioned letters patent as the clamping device of our invention, and of which we do not deem it necessary, therefore, to enter into a detailed description here. The tube-bolts *a a* are provided with ordinary stop-cocks, *b b*, the construction of which is well known. Over the outer ends of these bolts, stop-cocks and all, are the metal caps *c c*.

In charging a globe with an artificial atmosphere—such, for instance, as described in the above-mentioned letters patent—a long tube is passed through one of the tube-bolts *a*, so as to reach the upper portion of the globe, space being provided therefor. The lamp then being inverted the artificial atmosphere, entering by way of the other tube-bolt *a*, displaces the gaseous contents of the globe, which flow out by way of this long tube. When the globe is sufficiently well charged, and while the flow still continues, the

INVENTORS

William Edward Sawyer
Albon Man

long tube is slowly withdrawn, the outward flow of the gas preventing the entrance of atmospheric air during the operation. The long tube having been withdrawn, the stop-cock through which it had passed is closed. To fully seal the joint we pour melted beeswax into the opening outside of the stop-cock, and filling the nut *c* with melted beeswax we screw it up, so as to incase the entire external end of the tube with the beeswax, an opening, *d*, in the end of the cap permitting superfluous wax to exude. Thus the joint is hermetically sealed. To seal the outer tube-bolt, we close its stopcock *b*, disconnect the charging apparatus, and proceed to treat the bolt and cap as in the first instance. To further hermetically seal the entire globe, as by a hydraulic joint, we have recourse to a spun-metal cap, G′, fitting closely to the flange D, and held in place to it, if desired, by suitable pins or screws. The lower and smaller end of the spun cap, which is made open, is fitted with an insulating-plug, H, through which passes a metal screw, I, which, when all is in place, makes contact with metal strip *e*, fixed to a cap, *c*. The other cap *c* is connected by wire *g* with flange F, thence, by way of bolts E E, with flange D, and thence with cap G′. Thus to make connection of the lamp with a chandelier or a bracket, a metal arm of which is provided with an opening containing an exposed insulated contact-joint in its center, the two constituting the terminals of the conductors leading from the generator, all that is necessary is to screw the smaller end of the spun cap into the same until the insulated contact-joint and the screw I make connection, the electric current passing in by way of the spun cap and leaving by way of the screw I, or *vice versa*.

The application of the spun cap G′ is as follows: The lamp is first perfectly charged and the caps *c c* are put on, as already described. The spun cap G′ is then filled, or partially filled, with melted beeswax, and the lower extremity of the globe A, the stopper C, the clamping device, and all the parts appertaining
thereto are sunk into this fluid mass, which, upon cooling,
4102 effectually seals the lamp. We have spoken of beeswax as
the sealing agent; but it is clear that any other easily-fused material, or even an oil or other liquid, will answer the purpose equally well.

The spiral internal conductors shown and described in the letters patent referred to are somewhat unsightly. In place of them, we prefer the long conductors X X, (referring to Figs. 1 and 2), which are made of a copper ribbon polished or electroplated and folded in the manner shown, so as to form square gridiron-shaped uprights. These are screwed at their lower extremities to the tube-bolts *a a* by screws *á á*. To prevent electrical connections at the bends or at intermediate points, we place in the same small pieces of mica Y Y Y Y, and to render the rods firm and substantial we bind them at the ends with insulated wires Z Z Z Z. These conductors meet all the requirements of the spiral conductors of the letters patent referred to, and are much more pleasing to the eye. If desired, they may be constructed as shown in Fig. 3.

The diaphragm, to prevent downward radiation of the heat, as fully set forth in the aforesaid letters patent, may be of any infusible opaque insulating substance, or of metal, as shown in the present application. In our present invention it consists of two metal plates, P P, held together by bolts R R. The lower plate absorbs any possible radiation from the upper plate; but we may use more than two plates, or a single plate, if desired. Joining the two plates is a tube-bolt, Q, in which the round metal bar or rod L is free to slide. The bar L is capped with a platinum or iridium contact-piece, O. and is actuated by means of spring W, acting upon stirrup V, which has a bearing in the groove T of rod L, and is pivoted in nut U, to which the upper extremity of one of the conductors X is connected. The rod L thus allows for any contraction or expansion of the carbon pencil M. For this rod we have chosen the term the "anvil" of the lamp. The hammer consists of a metal bar, K, provided also with a platinum or iridium contact-piece, N, and it is held firmly in place by standard J′, to which, by way of its extension S, one of the conductors X is connected. The hammer-standard and its conductor are insulated in any of the well-known ways, preferably by the interposition of layers of mica at the points of contact.

The contact-points N and O may be of carbon, although we prefer platinum or iridium. In the drawings we have shown a method of combining several of the diaphragm-disks P, of metal, so as to constitute the conductors of the lamp. The disks are held together by small rods *h*, alternate plates being electrically connected, as shown, and insulated from the intermediate plates by the rods *h*, passing through the holes *i*, but not touching the sides thereof. The importance of a number of plates, P, to prevent downward radiation of heat is manifest.

To charge the globe we proceed as follows: The lamp being connected with a hydrogen-generator, we first exhaust the air, then we charge the globe with pure dry hydrogen; again we exhaust and charge with hydrogen, and this operation we repeat until the original gaseous contents of the globe are entirely replaced by the hydrogen. We then, in place of the hydrogen, connect the lamp with a generator of pure dry nitrogen, keeping the globe A constantly heated by having it immersed in a bath of hot water, exhausting the hydrogen. We fill the partial vacuum with nitrogen, or we may do it by displacement, and this operation we continue until the globe contains nothing but nitrogen, excepting such gases as may be occluded by the inclosed materials. To drive these out, we pass an electric current through the conductors *x x*. The carbon pencil M is intensely heated, and considerable heat having extended throughout all the inclosed material, thus driving out occluded gases, the operation of exhaustion and refilling with nitrogen is continued until finally all the elements of danger are eliminated from the lamp.

Having thus fully described our invention, what we claim as such, and desire to secure by letters patent, is—

1. In an electric lamp, the cap G′, provided with an insulated

contact, J, for the purpose of establishing the electric connection of the lamp with the terminals of the conductors leading from the generator when the lamp is set in a suitable holder, substantially as shown and described.

2. An internal conductor in an electric lamp consisting of strips of metal fluted or plain, insulated at their ends or heads with slips of mica or other suitable insulating material, and bound together to insure solidity of construction.

3. In an electric lamp, the combination of the diaphragm P, standard J′, sliding bar L, spring W, and stirrup V, in the manner substantially as described.

4. A sliding anvil, L, held in a socket, Q, and supported by a spring to carry the burner M and hold it against the hammer K, the contact-points to be of platinum or iridium, substantially as described.

5. The herein-described method of charging the globe of an electric lamp with nitrogen, consisting, first, of replacing the original gaseous contents of the globe with hydrogen, and then replacing the hydrogen with nitrogen.

6. In an electric lamp, two or more diaphragm-disks, as and for the purpose specified.

United States Patent Office.

William E. Sawyer, of New York, N. Y.

Electric Lamp.

Specification forming part of Letters Patent No. 219,771, dated September 16, 1879. Application filed April 23, 1879.

To all whom it may concern:

Be it known that I, William Edward Sawyer, of the city, county, and State of New York, have invented certain new and useful improvements in electric lamps and switches therefor, of which the following is a full, clear, and exact description.

My invention relates to that class of electric lamps in which light is produced by the incandescence of a solid conductor, notably of a carbon pencil interposed between two large carbon electrodes, and constituting a part of the electric circuit.

The general principles upon which such lamps are constructed and operate are sufficiently well understood to render a detailed description here unnecessary; and many of the features connected with the lamp of my present invention are fully shown and claimed in letters patent of the United States No. 205,144, dated June 18, 1878, granted jointly to me and Albon Man, of Brooklyn, New York.

Experience has shown that the carbon pencils employed in lamps of this description after a time cease to maintain a perfect contact or connection with their carbon-holders. The result is the development of the voltaic arc, and, because of the consequent instantaneous shortening of the carbon pencils by disintegration, the lamps must be taken apart, new pencils substituted, and the sealing-globe refilled with a carbon-preservative atmosphere. Experience has further shown that this shortening of the carbon pencil occurs usually at its contact with the upper holder, probably on account of the concentration of heat at that point, and that the shortening is limited in extent to one thirty-second of an inch.

In the poorest lamps of the incandescent order the life of a pencil of carbon prior to the occurrence of the voltaic arc is about five hours. In the best lamps the life of the pencil is in excess of two hundred hours. In some a life of probably a thousand hours will be attained, and it is barely possible that in some lamps the arc may never occur; but practically the manufacture of electric lamps for lighting by incandescence unprovided with a remedy for such destructive changes is so uncertain as to greatly impair the chances of the general introduction of electric lighting.

In my present invention I aim directly at this evil, correcting it whenever the voltaic arc occurs by at once establishing new points of contact. I place in the sealed globe a long pencil of carbon, which is fed up from the outside magnetically when necessary, and

INVENTOR.
W. E. Sawyer.

a lamp equipped with a pencil seven inches long will be equivalent to at least two hundred and twenty-four of the ordinary lamps, that being the number of times that new points of contact may be established. Hence it follows that as the poorest of the ordinary lamps will run for five hours without the occurr*a*nce of the voltaic arc, an equally poor "feeder" lamp provided with a pencil of carbon seven inches long will run for eleven hundred and twenty hours before renewal of the pencil will be necessary, or, say three hours a day for a year, and the best lamp will have a life of forty-four thousand eight hundred hours, or forty years with an average use of three hours per day.

(Here follow diagrams marked pp. 4103, 4104, 4105, & 4106.)

In the drawings accompanying and forming a part of this specification, figure 1 is a side view of the lamp; Fig. 2, a front view; Fig. 3, a top view of the upper works; Fig. 4, a top view of the feeding mechanism; and Fig. 5, a view of the lamp and its feeding-switch with their connections.

Like letters indicate like parts in all the drawings.

Referring to the drawings, Figs. 1, 2, 3, and 4, A is a glass globe, provided with a rim, A′. B is a glass stopper, ground to the same. C is a metal flange, supported on the rim A′ by any cushioning material, G. D is a wooden flange or cushion, supporting the metal flange E on stopper B. F F are screws, by which the flanges C and E are drawn together to clamp the stopper to the globe. All of this is fully shown and described in the letters patent hereinbefore referred to,

H is a copper diaphragm, into which are let three coiled springs, I, which keep the diaphragm from jarring against the glass, and at the same time hold it firmly in position. Passing through the diaphragm and secured by the nuts L′ is a long coiled copper tube, R, the lower end of which is brazed into off-set nut S, which is drawn to the stopper B by tubular bolt T, in which is a stop-cock, T′.

4108 In charging the globe with a carbon-preservative atmosphere, the gas enters the tubular bolt T, and passes upward through the off-set nut and the coiled tube R to the top of the globe, thus displacing the air, which finds its exit by way of the opening and stop-cock Q′ of the tubular bolt Q, which will be more fully described hereinafter.

Passing through the diaphragm and insulated from the same by mica washers K K is a standard, J, whose bent arm *g* carries a grooved carbon roller, *h*, pivoted at *h′*. Pivoted at *i′* in the bent arm *g* is a second bent arm, *i*, which carries a second grooved carbon roller, *j*, pivoted at *j′*. The standard J is clamped to the diaphragm by nut N on the bolt-extension L of the standard, the offset-piece M under the nut N serving as a connection with the long coiled solid conductor O, the lower end of which screws into the brass offset P, which serves both as the frame-work for a part of the feeding mechanism and as a nut for the tubular bolt Q.

Fixed to coiled conductor O is an arm, *l*, to which is attached the adjusting screw and nut *m m'*, by means of which the tension of spiral spring *n*, connecting with bent arm *i*, is regulated so as to bring the two carbon rollers *j h* together with the requisite pressure, the glass link *o* insulating the arm *l* from the bent arm *i* by way of spring *n*.

Screwing into and through the diaghragm H, on a line with the groove in the carbon rollers *j h*, is a slotted tube, *b*, in which travels a plunger, *a'*, to the offset *a* of which is attached a fine steel wire, Y, which passes upward over pulley Z, pivoted in Z', and thence downward over insulating wooden drum W^2 on shaft W^1, which rotates in standards P^1 P^1 of offset P. Surrounding the end of tube *b* which projects above the diaphragm is a carbon piece, *f*, cut away, as shown.

Pivoted in the diaphragm at *e'* is a bent arm, *e*, to which is fastened carbon piece f^1 by screw f^2. Fixed to the lower end of tube *b* is an arm, *c*, to which is attached the adjusting screw and nut d^1 d^2, by means of which the tension of spiral spring *d*, connecting with bent arm *e*, is regulated so as to bring the carbon jaws $f f^1$ together with the requisite pressure. Inclosed in the tube *b*, and passing between the carbon jaws $f f^1$ and the carbon rollers *j h*, is the long pencil of carbon *k*, by the incandescence of which, in that section which is between the jaws and the rollers, the light is produced; and by the rotation of the drum W^2 this pencil of carbon is fed upward as frequently as may be desired, the rollers *j h* turning slightly to allow for expansion and contraction of the pencil when heated and cooled.

Through the stopper B passes a third bolt, U, secured by nut L^2, and in the upper end of this bolt, at U', is pivoted a bent arm, V, to which is fixed a silver-plated iron disk, V^5, so as to bring the same directly over the end of tube-bolt Q. The tube-bolt Q is of soft iron, and being wound with insulated wire Q^3 constitutes an electro-magnet, one of the poles of which appears at Q^2. The armature V^5 is normally kept away from the magnet Q by spiral spring V^2, which is held in place by pin V^1 in bent arm V, the range of its movement being limited on the one hand by its coming in contact with the pole of the magnet Q^2, and on the other by the shape of that portion of the bent arm V which plays in bolt-head U.

Pivoted in bent arm V at the point V^3 is a pawl, V^6, which engages in the teeth of ratchet-wheel W on shaft W^1, and this pawl is held to its bearing by spring V^4, screwed to the bent arm. Thus at every vibration of the armature V^5 the pawl V^6 moves the ratchet-wheel one tooth, and thereby winds the wire Y upon the drum W^2 and feeds the carbon pencil upward, as will readily be understood without further explanation.

The pawl X, actuated by spiral spring X' from standard P^2, simply locks the rachet-wheel against back action as the pawl V^6 causes it to rotate.

The methods of making the several joints of the lamp air-tight are fully set forth in the letters patent hereinbefore referred to, and in letters patent No. 210,809, dated December 10, 1878, granted jointly to me and to Albon Man, of Brooklyn, New York; and as the same constitute no part of my present invention, I have deemed it unnecessary to again describe them.

Referring now to Fig. 5, in which the connections of the lamp with its feeding-switch are shown, p is a spun metal-cup enclosing the entire base of the lamp, and provided with a threaded opening, by means of which it is screwed to any fixture, s. The current coming from the + point is conducted through the insulating-piece q to the magnet Q, and passes thence by way of conductor O, the carbon pencil k, and conductor R to the bolt T, thence to the spun-metal cup, standard s, and the coils of the electro-magnet u outward to the — point. The armature v of magnet u, pivoted at v', is thus drawn away from the stop x against the force of spiral spring u', let into one of the poles of the magnet. Connected with the armature v outside of the lamp is the conductor leading to magnet Q. When the magnet u is not energized its armature v, forced upward by spring u', makes connection with the contact-piece w^2 of lever w, which is pivoted at w^1, and normally forced against stop x by spring w^3, and in that relation the current passes from the + point around the lamp to armature v, lever w, and outward at the — point. When the circuit of the carbon pencil k is broken the armature v is released and the above circuit established, thus preventing interruption of the light in other lamps in circuit.

One end of the helix of magnet Q is connected with the magnet, as shown. The other end passes through insulating piece r in spun cup p, and thence to crank z, provided with cam y on pin y'. To
energize the magnet Q and feed up the carbon pencil, the
4109 crank z is — lever w, raises the latter from its connection with
armature v; and instead of the current flowing from the +
point to armature v, lever w, and outward at — point, it flows by way of the helix of magnet Q to cam y and lever w outward, thus energizing magnet Q and moving the ratchet-wheel, which feeds the carbon pencil one tooth, and so on until the circuit of the carbon pencil is re-established, when armature v is again attracted and the lamp once more operates.

In describing the lamp of my present invention, I have not considered it necessary to show its combination with a switch for graduating the light, or to indicate the many changes that may be made in the feeding-switch, such as rendering its action automatic by means of an electro-magnetic vibrator or of a circuit-breaker operated in any manner and controlled by magnet u. If desired, the feeding-switch may be combined in the base of the lamp, and there may be two magnets, one, so long as the circuit of the pencil of carbon exists, operating to open the circuit of the other or feeding magnet, and, when the circuit of the carbon pencil no longer exists, operating to permit the feeding-magnet to vibrate its armature until the circuit of the pencil is re-established.

I would have it understood that I disclaim in my present application the broad matter of a switch operating when the circuit of a lamp is interrupted to cut out, short-circuit, or throw a shunt around the lamp.

Having thus fully described my invention, what I claim as such, and desire to secure by letters patent, is—

1. In an electric lamp, the combination, first, of the diaphragm H, tube *b*, hinged piece *e*, and jaws $f\ f^1$; second, of the diaphragm H, tube *b*, hinged piece *e*, jaws $f\ f^1$, and spring *d;* third, of the diaphragm H, the tube *b*, and the two carbon-holders *h* and *j;* fourth, of the diaphragm H, the two carbon-holders f^1 and *j*, free to move laterally, and the two carbon-holders *f* and *h*, prevented from moving laterally; fifth, of the two holders f^1 and *j*, free to move laterally, and the two holders *f* and *h*, prevented from moving laterally.

2. In an electric lamp in which light is produced by the incandescence of a carbon piece, rod, or pencil, the combination, first, of the carbon-holding tube *b*, the jaws $f\ f^1$, the carbon piece, rod, or pencil *k*, the follower or plunger a', the flexible wire Y, the pulley Z, and the drum W^2, constructed and operating substantially as shown and described; second, of the standard J, the rigid carbon-holder *g*, and the jointed carbon-holder *i;* third, of the carbon-holding tube *b*, the upper and lower contact jaws, $f\ f^1$ and *h j*, and an electric apparatus operating to feed the incandescent carbon piece, rod, or pencil to a new contact when required or desired; fourth, of the tubular conductor R, the offset-nut S, and tube-bolt T; fifth, of the bolt Q, offset-nut P, standards $P'\ P'$, shaft W^1, and ratchet-wheel W; sixth, of the magnet Q and bolt U, passing through the stopper B of the lamp, as and for the purpose specified.

3. In an electric lamp in which light is produced by the incandescence of a carbon piece, rod, or pencil, the combination of the diaphragm H and springs I, as and for the purpose specified.

4. The feeding-switch *u*, *v*, *w*, and *y*, in combination with the magnet Q.

5. The combination, with an electric lamp in which a carbon rod, piece, or pencil is fed to a new contact when required or desired, of a switch which shifts the current into and from the coils of an electro-magnet by which the feeding mechanism is actuated without destroying the continuity of the circuit.

United States Patent Office.

Thomas A. Edison, of Menlo Park, New Jersey.

Electric Lamp.

Specification forming part of Letters Patent No. 223,898, dated January 27, 1880. Application filed November 4, 1879.

To all whom it may concern:

Be it known that I, Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, have invented an improvement in electric lamps, and in the method of manufacturing the same, (case No. 186,) of which the following is a specification.

The object of this invention is to produce electric lamps giving light by incandescence, which lamps shall have high resistance, so as to allow of the practical subdivision of the electric light.

The invention consists in a light-giving body of carbon wire or sheets coiled or arranged in such a manner as to offer great resistance to the passage of the electric current, and at the same time present but a slight surface from which radiation can take place.

The invention further consists in placing such burner of great resistance in a nearly-perfect vacuum, to prevent oxidation and injury to the conductor by the atmosphere. The current is conducted into the vacuum-bulb through platina wires sealed into the glass.

The invention further consists in the method of manufacturing carbon conductors of high resistance, so as to be suitable for giving light by incandescence, and in the manner of securing perfect contact between the metallic conductors or leading-wires and the carbon conductor.

Heretofore light by incandescence has been obtained from rods of carbon of one to four ohms resistance, placed in closed vessels, in which the atmospheric air has been replaced by gasses that do not combine chemically with the carbon. The vessel holding the burner has been composed of glass cemented to a metallic base. The connection between the leading-wires and the carbon has been obtained by clamping the carbon to the metal. The leading-wires have always been large, so that their resistance shall be many times less than the burner, and, in general, the attempts of previous persons have been to reduce the resistance of the carbon rod. The disadvantages of following this practice are, that a lamp having but one to four ohms resistance cannot be worked in great numbers in multiple arc without the employment of main conductors of enormous dimensions; that, owing to the low resistance of the lamp, the leading-wires must be of large dimensions and good conductors, and a glass globe cannot be kept tight at the place where the wires pass in and are cemented; hence the carbon is consumed, because there must be almost a perfect vacuum to render the carbon stable, especially when such carbon is small in mass and high in electrical resistance.

The use of a gas in the receiver at the atmospheric pressure, although not attacking the carbon, serves to destroy it in time by "air-washing," or the attrition produced by the rapid passage of the air over the slightly-coherent highly-heated surface of the carbon. I have reserved this practice. I have discovered that even a cotton thread properly carbonized and placed in a sealed glass bulb exhausted to one-millionth of an atmosphere offers from one hundred to five hundred ohms resistance to the passage of the current, and that it is absolutely stable at very high temperatures; that if the thread be coiled as a spiral and carbonized, or if any fibrous vegetable substance which will leave a carbon residue after heating in a closed chamber be so coiled, as much as two thousand ohms resistance may be obtained without presenting a radiating-surface greater than three-sixteenths of an inch; that if such fibrous material be rubbed with a plastic composed of lamp-black and tar, its resistance may be made high or low, according to the amount of lamp-black placed upon it; that carbon filaments may be made by a combination of tar and lamp-black, the latter being previously ignited in a closed crucible for several hours and afterward moistened and kneaded until it assumes the consistency of thick putty. Small pieces of this material may be rolled out in the form of wire as small as seven-one-thousandths of an inch in diameter and over a foot in length, and the same may be coated with a non-conducting non-carbonizing substance and wound on a bobbin, or as a spiral, and the tar carbonized in a closed chamber by subjecting it to high heat, the spiral after carbonization retaining its form.

All these forms are fragile and cannot be clamped to the leading-wires with sufficient force to insure good contact and prevent heating. I have discovered that if platinum wires are used and the plastic lamp-black and tar material be molded around it in
4112 the act of carbonization there is an intimate union by combination and by pressure between the carbon and platina, and nearly perfect contact is obtained without the necessity of clamps; hence the burner and the leading-wires are connected to the carbon ready to be placed in the vacuum-bulb.

When fibrous material is used the plastic lamp-black and tar are used to secure it to the platina before carbonizing.

By using the carbon wire of such high resistance I am enabled to use fine platinum wires for leading-wires, as they will have a small resistance compared to the burner, and hence will not heat and crack the sealed vacuum-bulb. Platina can only be used, as its expansion is nearly the same as that of glass.

By using a considerable length of carbon wire and coiling it the exterior, which is only a small portion of its entire surface, will form the principal radiating-surface; hence I am able to raise the specific heat of the whole of the carbon, and thus prevent the rapid reception and disappearance of the light, which on a plain wire is prejudicial, as it shows the least unsteadiness of the current by the flickering of the light; but if the current is steady the defect does not show.

I have carbonized and used cotton and linen thread, wood splints,

T. A. EDISON.

papers coiled in various ways, also lamp-black, plumbago, and carbon in various forms, mixed with tar and kneaded so that the same may be rolled out into wires of various lengths and diameters. Each wire, however, is to be uniform in size throughout.

If the carbon thread is liable to be distorted during carbonization it is to be coiled between a helix of copper wire. The ends of the carbon or filament are secured to the platina leading-wires by plastic carbonizable material, and the whole placed in the carbonizing-chamber. The copper, which has served to prevent distortion of the carbon thread, is afterward eaten away by nitric acid, and the spiral soaked in water, and then dried and placed on the glass holder, and a glass bulb blown over the whole, with a leading-tube for exhaustion by a mercury-pump. This tube, when a high vacuum has been reached, is hermetically sealed.

With substances which are not greatly distorted in carbonizing, they may be coated with a non-conducting non-carbonizable substance, which allows one coil or turn of the carbon to rest upon and be supported by the other.

(Here follows diagram marked p. 4110.)

In the drawings, figure 1 shows the lamp sectionally. *a* is the carbon spiral or thread. *c c'* are the thickened ends of the spiral, formed of the plastic compound of lamp-black and tar. *d d'* are the platina wires. *h h* are the clamps, which serve to connect the platina wires, cemented in the carbon, with the leading-wires *x x*, sealed in the glass vacuum-bulb. *e e* are copper wires, connected just outside the bulb to the wires *x x*. *m* is the tube (shown by dotted lines) leading to the vacuum-pump, which, after exhaustion, is hermetically sealed and the surplus removed.

Fig. 2 represents the plastic material before being wound into a spiral.

Fig. 3 shows the spiral after carbonization, ready to have a bulb blown over it.

I claim as my invention—

1. An electric lamp for giving light by incandescence, consisting of a filament of carbon of high resistance, made as described, and secured to metallic wires, as set forth.

2. The combination of carbon filaments with a receiver made entirely of glass and conductors passing through the glass, and from which receiver the air is exhausted, for the purposes set forth.

3. A carbon filament or strip coiled and connected to electric conductors so that only a portion of the surface of such carbon conductors shall be exposed for radiating light, as set forth.

4. The method herein described of securing the platina contact-wires to the carbon filament and carbonizing of the whole in a closed chamber, substantially as set forth.

Signed by me this 1st day of November, A. D. 1879.

Correction in Letters Patent No. 223,898.

DEPARTMENT OF THE INTERIOR,
UNITED STATES PATENT OFFICE,
WASHINGTON, D. C., *December* 18, 1883.

In compliance with the request of the party in interest, letters patent No. 223,898, granted January 27, 1880, to Thomas A. Edison, of Menlo Park, New Jersey, for an improvement in " electric lamps," is hereby limited so as to expire at the same time with the patent of the following named, having the shortest time to run, viz: British patent dated November 10, 1879, No. 4576; Canadian patent dated November 17, 1879, No. 10654; Belgian patent dated November 29, 1879, No. 49884; Italian patent dated December 6, 1879, and French patent dated January 20, 1880, No. 133,756.

It is hereby certified that the proper entries and corrections have been made in the files and records of the Patent Office.

This amendment is made that the United States patent may conform to the provisions of section 4887 of the Revised Statutes.

BENJ. BUTTERWORTH,
Commissioner of Patents.

Approved:

M. L. JOSLYN,
Acting Secretary of the Interior.

4115

UNITED STATES PATENT OFFICE.

ALBON MAN, of Brooklyn, New York.

Electric Lamp.

Specification forming part of Letters Patent No. 227,118, dated May 4, 1880. Application filed March 31, 1880. (No model.)

To all whom it may concern:

Be it known that I, Albon Man, of Brooklyn, in the county of Kings and State of New York, have invented certain new and useful improvements in electric lamps, of which the following is a description in such full, clear, exact, and concise terms as to enable any one skilled in the arts or sciences to which it appertains or with which it is most nearly connected to make and use the same, reference being had to the annexed drawings, making part of this specification, and to the figures and letters of reference marked thereon.

In incandescent electrical lights positive electrical connection equal to or greater than the conducting power of the incandescent pencil must be made with the pencil in order to prevent the occurrence of an electrical arc, which immediately destroys the pencil itself. Tension, torsion, or compression upon the pencil acts in the end, by continual repetition, to destroy it.

Expansion and contraction of the electrical supporters or connections of the pencil, causing or tending to cause motion of the pencil in any direction other than that in which it can freely move, puts tension upon it, and sooner or later destroys it. The more yielding the parts sustaining the pencil (while at the same time making electrical connections) can be made the smaller the pencil or light-giving portion may be made, and the smaller the pencil the greater the amount of light that may be obtained by passing a given current of electricity through it.

It is evident that one end of the pencil may be rigidly held if the other is flexibly connected; but at the same time such other end must be sustained laterally and prevented from vibrating or moving in any direction other than in the line of its axis.

I prefer to place the pencil in an upright position, as in this position it is less likely to give way under the high heat to which it is subjected, and it can be more readily attached to its supports, and such supports in this position do not so much interfere with the radiation of its light.

It is to accomplish these results and purpose that I have devised the following method of making and supplying the incandescent portion of an electric lamp, that the expansion and contraction of the two parts caused by the heat of electricity shall be equal, the expansion of one part neutralizing the expansion of the other and the contracting of one part neutralizing the contraction of the other in all directions, except in the direction of the axis of the pencil or light-giving portion of the circuit supported by these parts.

My invention appertains to sealed incandescent electric lamps; and it consists, first, of hermetically joining and sealing, with a tight metal joint, the globe of the lamp, made of glass, porcelain, or other similar material, through which the light is radiated, to its base, bottom, stopper, and all the other parts or fittings appertaining to it, by which it is made a completely hermetically-sealed lamp, while providing at the same time for free flow of the electric current or circuit through the lamp, and also for exhausting the atmosphere and charging the lamp with a carbon-preservative gas or atmosphere; second, of a symmetrical suspending electrical connection to the top part of the incandescent carbon pencil, consisting of a divided metallic conductor arranged to embrace, hold, and support the pencil, and to equally divide the current going to and from it, so that the expansion and contraction of the supporting parts shall be equal, the expansion occasioned by the passage of the electric current through one part of the supporting-conductor being equalized by the passage of an equal amount through the other part, the object being to maintain all the supporting parts of the pencil in their normal relative position—that is, not affected in their relative position by the heat of the current through them, or by the heat of the incandescent portion of the lamp; third, of an electrical connection and support to the lower portion of the pencil, consisting of a divided conductor, whose expansion and contraction, occasioned by the passage of the current, will equalize each other, and thus prevent any lateral motion of the pencil, while at the same time it is left free to expand and contract in the line of its axis; fourth, of an electrical suspending-
4116 support for the carbon pencil of an incandescent electric
lamp, consisting, substantially, of a yoke constructed and arranged symmetrically with reference to the pencil, as a conductor of heat and electricity, that the only motion given to the pencil by expansion and contraction through its support shall be in the line of its axis; fifth, of an electrical connection with the opposite end of a suspended carbon pencil, consisting of two semi-cylindrical grooved pieces of carbon united upon the pencil by wires or a clamping-ring, and in the embrace of yielding metallic connection, equally divided and disposed around it in such relation and manner that the expansion and contraction on all sides and in all parts shall be equal, in so far as there may be any tendency to throw the pencil out of its normal position laterally; sixth, of an electrical connection to the top and bottom end of the carbon pencil of an incandescent electric lamp, consisting of equally-divided metal electric conductors, united to the pencil at top and bottom by dividing and intervening pieces of carbon, the bottom conductor being not only equally divided, but also made yielding to avoid weight, pressure, and tension upon the pencil; seventh, of an electrical connection to the lower end of the carbon pencil, consisting of a yielding conductor divided equally around it, and arranged to allow it freedom of motion in the line of its axis and at the same time avoid all lateral or torsionate strain upon it.

A detail description of the first part of my invention is as follows:

(Here follow diagrams marked pp. 4113 and 4114.)

In the drawings the globe of the lamp is shown by A. It is made of glass, porcelain, or any similar material suitable for the radiation of light. The base or stopper of the lamp is shown by B. It may be made of any of the materials aforesaid, or it may be made wholly of metal; but if made of metal proper provisions must be made for insulating the conducting-wires through it in and out of the lamp.

Assuming, now, the base or stopper of the lamp to be made of glass, the joint between it and the globe is made and sealed as follows:

The surface of the globe at *a* and *b* and the surface of the stopper or base at *c d* and *e f* are first metallized—that is, covered or filled with metal—either by fire-gilding, silvering, or platinizing in the ordinary method of fire-gilding, silvering, platinizing, or otherwise metallizing the surface of glass, porcelain, crockery, stoneware, and other similar material. These parts, having been thus metallized, are put into an electroplating bath or solution and electroplated by the ordinary process of electroplating. In the base of the lamp a narrow metal ring, *c*, is fitted, upon which the bottom end of the globe sets. The parts, being thus prepared, are brought together and are united, joined, and sealed with solder applied to the electroplated parts of the base and globe of the lamp.

Instead of first electroplating the several parts and afterward uniting them with solder, as above described, I can secure them together after metallizing them, and put them thus united in the electroplating-bath and electroplate directly upon the metallized surface and over the joints or parts of contact, thus making a solid metal joint by electroplating instead of soldering.

The drawings show a tube, D, which may be of glass or metal, and which is joined with a tight joint to the base or stopper of the lamp, in the same way the globe is joined to the base. The object of this tube is to furnish means to charge the lamp with the carbon-preservative atmosphere, or to exhaust the air out of it.

In case the tube be made of glass or porcelain, it must be thoroughly metallized and electroplated in the joint to make it a conductor of electricity, and means (connecting-post) must be supplied to connect the wires; but there is no objection to making the tube of metal and joining it to the base or stopper, as above described, the wire E being connected to the upper end of the tube and the wire F to the metallic ring *c* in contact with the electroplating and solder of the joint, the positive and negative poles being applied as shown, the connection being made by any of the well-known means.

My intention is to make the tube D of lead or other soft metal and use it as part of the conducting-circuit, and as means of finally sealing the lamp after it has been exhausted of air and charged with a carbon-preservative gas or atmosphere, the conducting-wire to be connected to the outer and inner end of the tube, or carried through the tube or its wall into the globe of the lamp, the sealing being accomplished by forcing the walls of the tube together and sealing it with a blow-pipe or with solder.

The second part of my invention is shown in the drawings, more especially by Figs. 4, 5, and 7. It consists of a divided conductor, the two parts of which are shown by H H. These conductors are made of metal, of equal size and of equal conducting power. Their upper ends are formed in the shape of a yoke, the two parts of which are made exactly symmetrical with reference to each other, and are clamped by means of screws upon two grooved semicircular pieces of carbon, G, in which the illuminating-pencil *o* is held. These pieces of semi-cylindrical grooved carbon are to be made exactly of the same size, divided in the center longitudinally, the dividing-joint N to be arranged upon the line of the joint of the yoke, as shown by Figs. 6 and 7.

Upon the bottom ends of the divided conductors H H a screw-shank is made, that passes through holes in the soapstone diaphragm-plate J and screws into the respective ends of a semicircular
4117 metal conductor, P, set in the bottom side of the diaphragm-plate J, as shown by Figs. 4 and 9 of the drawings.

The points of contact between the lower ends, H, of the divided conductor with the plate P are exactly equidistant from the +-point Q, the two ends of the plate from that point being made of exactly the same volume and conducting power. By these means the current entering at Q is made to divide equally and enter the illuminating-pencil *o* from both sides with equal intensity, equally heating and expanding the two branches of the conductor, from the top of which the carbon pencil is suspended, thus avoiding all lateral or torsionate strain upon the illuminating-pencil, while at the same time it is left free to expand and contract upon the line of its longitudinal axis, the dividing conductor acting as a divided electrical support of equal expanding capacity, between which the carbon pencil is suspended, and by which all lateral or torsionate strain upon it is avoided.

The third point of my invention is more especially illustrated by Figs. 8 and 10 of the drawings, though its connection with the other parts of the invention is especially shown by Figs. 4 and 5, and incidentally by the other figures of the drawings. It consists of a divided metal conductor composed of strips of thin metal, forged and arranged substantially in the form of two elliptical springs set across each other, as shown by I, Figs. 8 and 10, for the support of the lower end of the carbon pencil. These elliptical springs or strips of metal are all of equal length, size, volume, and conductivity electrically. They are set across each other equidistant apart, and are held to the diaphragm-disk J by means of a screw, L, reaching down and making contact with the piece U, to which the —-pole is connected at Q′.

The top ends of the elliptics are turned up, as at *k*, forming together an open slotted socket of the ends of the several strips of metal, into which is inserted a cylindrical piece of carbon, G′, divided longitudinally in the center, and grooved, as shown by R, to receive the lower part of the carbon pencil. The carbon-support G′ is secured in the divided elliptical conductors and the pencil in the carbon-support by means of wire wrapped around the slotted socket, or by means of a clamping-ring upon the socket, as may be most convenient. By these means the lower part of the carbon pencil is supported upon a divided electric conductor yielding and equal on all sides, and the carbon pencil is allowed to expand and contract in the line of its axis, while at the same time all tensile, torsionate, or lateral strain upon it is avoided.

The shape and size of the elliptical or divided conductors must be substantially alike on all sides, that the expansion, contraction, and electrical conducting power may be alike on all sides and the normal position of the carbon pencil with reference to its connections and supports be equally maintained.

The fourth, fifth, sixth, and seventh parts of my invention are fully described in the description given above of the second and third parts of it. A description of these two parts includes a description of the above-mentioned four.

Having described my invention, I claim and desire to secure by letters patent—

1. Hermetically sealing and joining the globe and stopper of an electric lamp by electroplating and solder, or by electroplating alone, applied to the metallized surfaces of the parts joined, preserving at the same time the insulation of the electric circuit through the lamp, substantially as described.

2. A soft-metal tube hermetically joined with a metal joint to the glass bottom or stopper, as part of the electric circuit in the lamp, and for the purpose of filling, exhausting, and finally sealing it, substantially as described.

3. A symmetrical suspending electrical connection to the top part of the incandescent carbon pencil, consisting of a divided metallic conductor arranged to embrace, hold, and support the pencil, and to equally divide the current going to and from it, so that the expansion and contraction of the supporting parts shall be equal, substantially as described.

4. An electrical connection and support to the lower portion of the pencil, consisting of a divided conductor whose expansion and contraction, occasioned by the passage of the current, will equalize each other, and thus prevent any lateral motion of the lower portion of the pencil, while at the same time it is left free to expand and contract in the line of its axis, substantially as described.

5. An electrical suspending support for the carbon pencil of an incandescent electric lamp, consisting, substantially, of a yoke constructed and arranged symmetrically with reference to the pencil, as a conductor of heat and electricity, that the only motion given to the pencil by expansion and contraction through its support shall be in the line of its axis.

6. An electrical connection with the opposite ends of a suspended carbon pencil, consisting of two semi-cylindrical grooved pieces of carbon united upon the pencil by wire or a clamping-ring, and in the embrace of yielding metallic connection, equally divided and

disposed around it in such relation and manner that the expansion and contraction on all sides and in all parts shall be equal, in so far as there may be any tendency to throw the pencil out of its normal position laterally.

7. An electrical connection to the top and bottom end of the carbon pencil of an incandescent electric lamp, consisting of equally-divided metal electric conductors united to the pencil at top and bottom by divided and intervening pieces of carbon, the bottom conductor being not only equally divided, but also made yielding to avoid weight, pressure, and tension upon the pencil. 4118

8. An electrical connection to the lower end of a yielding conductor, divided equally around it, and arranged to allow it freedom of motion in the line of its axis and at the same time avoid all lateral or torsionate strain upon it.

UNITED STATES PATENT OFFICE.

WILLIAM E. SAWYER, of New York, and ALBON MAN, of Brooklyn, N. Y., assignors to Electro-Dynamic Light Company.

Carbon for Electric Lights.

Specification forming part of Letters Patent No. 229,335, dated June 29, 1880. Application filed November 22, 1878.

To all whom it may concern:

Be it known that we, William Edward Sawyer, of the city, county, and State of New York, and Albon Man, of Brooklyn, county of Kings, and State aforesaid, have jointly invented certain improvements in carbons for electric lights; and we do hereby declare the following to be a description of the same, and of the manner and process of making, constructing, and using them, in such full, clear, concise, and exact terms as will enable any person skilled in the art or science to which it appertains, or with which it is most nearly connected, to make, construct, and use the same, reference being had to certain letters patent of the United States heretofore granted to us for certain inventions hereunto appertaining, and to which especial reference will hereinafter be made.

Our invention consists of a new article of manufacture, consisting of an improved illuminating conductor for electric lamps, composed of consolidated carbon created by electric action.

In letters patent of the United States No. 205,144, granted to us, we have shown and described an electric lamp, in which a pencil of carbon is heated to in candescence in a nitrogen or other carbon-preservative atmosphere.

One of the principal obstacles to successful electric lighting by incandescence is the dissociated character of nearly all obtainable carbon. In most of such carbon there is danger of fracture as well as of the establishment of the voltaic arc; and, furthermore, the carbon, unless specially prepared by our process, naturally occludes sufficient air or oxygen to render its consumption a mere question of time, since, as fully set forth in the letters patent referred to, the least quantity of oxygen in a sealed lamp is sufficient to combust an indefinite quantity of carbon.

As is well known, carbon suitable for electric lighting by the voltaic arc is naturally produced in gas retorts; but generally the rods of carbons used in the "regulator lamps," so-called, are molded from the powdered material. Neither the one nor the other quality of carbon is suitable for electric lighting by incandescence. In both there is a lack of homogeneity. The pencil is not sufficiently hard and dense, because, in the first place, the heat required to produce the proper character of carbon is as high as 7,000° Fahrenheit, and such a temperature is not obtainable in the retort; and in the second place the mechanical subdivisions of the material and the pressure necessary to produce the perfect article are practically unattainable. Carbon of the ordinary sort, when heated by the electric current, exhibits points and lines of unequal brilliancy. Carbon prepared by our process, when so heated, glows with a uniform brilliancy throughout.

We have found that a pencil of carbon immersed in a hydrocarbon gas or liquid and heated to an extremely high temperature by the voltaic current is not itself attacked, but decomposes the surrounding matter, the carbon of which enters and fills up its pores to an extent impossible except with matter in a very attenuated state, and deposits a perfectly homogeneous layer, generally of a bright gray color, upon the exterior surface. As the carbon increases in size more current is required to maintain its temperature, and if the current is gradually increased in accordance with the demand for it there is appearingly no limit to the increase in mass of the homogeneous exterior deposit. Carbon pencils may be cut from this deposit, or the original pencil with its coating may be used in the lamps.

In this process it would seem that the carbon is never in contact with the liquid in which it is immersed, but surrounded by a carbon gas of a very high temperature. Naphtha, turpentine, beeswax, balsam, and most oils, if pure, operate satisfactorily. Almost any hydrocarbon, in fact, will answer.

We do not confine ourselves to the treatment of carbon alone, since it is obvious that many infusible substances, non-conductors of electricity, may be heated in hydrocarbon liquids or gases, so as to render them conductors of electricity—as, for instance, a tube of lime inclosing a pencil of carbon, through which the electric current is caused to circulate.

4120 In the letters patent hereinbefore referred to we have described a method of charging a sealed globe with pure nitrogen gas. We will suppose that the pencil of carbon, held between two carbon pieces of greater mass than that of the pencil, as shown in the said letters patent, is immersed in the hydrocarbon liquid and heated in the manner already described. Being then cleansed in alcohol, the pencil and its holders, without having been disturbed, are placed in the globe, in which they are to be hermetically sealed. The globe is charged with pure nitrogen, and then, while still allowing pure nitrogen to flow into and out of the globe, we heat the carbon to incandescence, thus driving out all impurities and occluded gases, which are carried out of the lamp by the current of nitrogen.

With this operation the preparation of the carbon is completed, and the lamp, now being hermetically sealed, as described in the letters patent referred to, is ready for use.

Having thus described our invention, we claim and desire to secure by letters patent—

Carbon consolidated and purified by electrically treating it, in combination with a carbonaceous substance, for the production of electric burners.

UNITED STATES PATENT OFFICE.

WILLIAM E. SAWYER, of New York, and ALBON MAN, of Brooklyn, N. Y., assignors to Electro Dynamic Light Company.

Electric Switch.

Specification forming part of Letters Patent No. 229,476, dated June 29, 1880. Application filed December 5, 1878.

To all whom it may concern:

Be it known that we, William Edward Sawyer, of the city, county, and State of New York, and Albon Man, of Brooklyn, county of Kings, and State aforesaid, have jointly invented certain new and useful improvements in electric switches for dividing and regulating the application of electric currents to electric lamps; and we do hereby declare the following to be a description of our invention, and of the manner and process of making, constructing, and using the same, in such full, clear, concise, and exact terms as to enable any person skilled in the art or science to which it appertains, or with which it is most nearly connected, to make, construct, and use the same, reference being had to the accompanying drawings, making part of this specification, and to the figures and letters of reference marked thereon, and also to letters patent allowed to us for switches for electric lights, November 15, 1878.

In this switch the mode of operation in its relation to the lamp is substantially the same as that of the letters patent allowed to us as aforesaid; but this switch differs from that in its mechanical construction and in the material of which it is constructed, by which all danger or inconvenience arising from the heat of the current is avoided.

The frame of this switch is composed of soapstone or other non-conductor of heat that can be readily worked in the desired form, and instead of resistances formed of metallic conductors, as in the patent above referred to, we employ either broken or powdered carbon or carbon rods packed in tubes formed or set in the frame of the switch.

(Here follow diagrams marked pp. 4121 & 4122.)

Reference being had to the drawings, A is a disk of plaster of paris, soapstone, or other heat-resisting material, perforated, as shown in Fig. 6, the black circles being those which are filled with carbon, the others being for the rods and connections by which the several parts are clamped together.

On the top side of the disk are set fourteen metallic pieces, I, and on the bottom side thirteen similar pieces, J. These pieces are arranged as shown, and drawn firmly together and down upon the disk A by screw-rods I′, the position they hold with respect to each other being clearly shown in Fig 1, wherein the full lines represent the pieces I upon the top of the disk and the dotted lines the pieces J upon the under side of the disk. The enlarged ends of the pieces I J cover the holes N O through the disk, the pieces I acting as a stopper to the upper end of the hole. The hole being packed with carbon K, Fig. 4, the plunger L is put into the lower end, and by means of screw M in pieces J the plunger L is caused to exert any required pressure upon the carbon, thus making perfect connection with the carbon and enabling its resistance to be changed, if desired.

Through hole B^2 passes a stud, B, drawn down upon the disk A by nut B′ on the under side of the disk, and turning upon this stud is a metallic disk, C, Figs. 2 and 3, through the hole B^3 of which the stud passes, the disk C being secured in place by nut B^4, Fig. 2, on the upper end of stud B.

On the disk C are two brackets, D D, drilled partly through from the under side of the disk. In the circular cavities thus made, actuated by spiral springs E′, work the two plungers E, which, as the disk is turned, make connection with the faces of the pieces I. The disk is further provided with eight pins, F, in which the pin G′ of crank-key G, working on stud H, engages, precisely the same as in the letters patent referred to. Referring to those letters patent, the current, as shown in Fig. 1, enters from the + side at the stud B, and thence through disk C and its plunger E, and when the lamp is not in circuit it passes outward by way of piece I (numbered 1) and the carbon resistance N, which has the same resistance as that of the lamp. When the lamp is fully lighted the current passes outward by way of piece I, (numbered 14,) and through the lamp.

The object of the piece P is merely to keep the plungers E from dropping out of place. Supposing the resistance of the lamp is .95 ohm, the resistance N, Fig. 6, corresponding to piece I, No. 1, of Fig. 1, is .95 ohm. When the lamp is completely out of the circuit one of the studs E is bearing upon piece I, No. 1, and the other stud E is bearing upon the blank piece P, with which there is no connection. 4124 A single turn of the crank brings the studs upon pieces I, Nos. 2 and 8, and the current divides, three-fourths of it flowing, by way of pieces 2, carbon resistance N′, of $.31\frac{2}{3}$ ohm, piece J, and bolt I′, to piece I, No. 1, and resistance N, of .95 ohm, outward, and one-fourth of it flowing, by way of piece 8, carbon resistance O, of 1.9 ohm, and thence by piece J and bolt I′ to piece 9; thence through carbon resistance O′, of .38 ohm, and so on through carbon resistances O^2, of $.25\frac{1}{3}$ ohm, O^3, of $.18\frac{2}{21}$ ohm, O^4, of $.07\frac{5}{21}$ ohm, and O^5, of $.06\frac{1}{3}$ ohm, and thence, through piece J and bolt I′, to piece 14 and the lamp. The total resistance of the first or shunt circuit is therefore $1.26\frac{2}{3}$ ohm, and that of the lamp circuit, including the lamp, is 3.8 ohms, making the joint resistance .95 ohm. The resistance of N^2 is $.63\frac{1}{3}$ ohm, N^3 $.63\frac{1}{3}$ ohm, N^4 $1.26\frac{2}{3}$ ohm, N^5 3.8 ohms, and N^6 7.6 ohms, making a sum total of resistances on the shunt side of 15.2 ohms.

Without following out the various changes, which are fully set forth in the letters patent referred to, suffice it to say that when one plunger E is bearing upon piece I, No. 1, the other plunger is bearing upon blank piece P, and that the plungers thereafter take position as follows: upon 2 and 8, 3 and 9, 4 and 10, 5 and 11, 6 and 12, 7 and 13, and lastly blank piece P and 14, when the entire current is directed through the lamp.

Having thus fully described our invention, we claim and desire to secure by letters patent—

1. An electric switch consisting of a frame composed of soapstone or plaster, or other insulating material, also suitable to resist the transmission of heat, fitted with carbon resistances and combined with metal contact-joints and conductors arranged in relation to each other to regulate the application and division of the current to the lamp, as set forth, and at the same time avoid danger or inconvenience from the heat of the current.

2. A circular disk, A, fitted with packed carbon resistances, as set forth.

3. A disk, A, fitted with pieces I and J, clamped to the disk, as set forth.

UNITED STATES PATENT OFFICE

JOSEPH W. SWAN, of Newcastle-upon-Tyne, England.

Electric Lamp.

Specification forming part of Letters Patent No. 233,445, dated October 19, 1880. Application filed April 12, 1880. (No model.)

To all whom it may concern:

Be it known that I, Joseph Wilson Swan, chemist, of Newcastle-upon-Tyne, England, have invented an improvement in electric lamps, of which the following is a specification.

My invention relates to that kind of electric lamp in which light is produced by the incandescence of a continuous conductor of carbon inclosed in an exhausted glass bulb, and provides means for increasing the durability of the said kind of lamp.

The first part of my invention has for its object to prevent the cracking and leakage of the glass bulb or inclosing vessel in consequence of the heating and cooling of the conducting-wires, which, when simply sealed into the glass globe, cause it to crack and leak at or near the junction of the wires and glass.

The devices employed for obtaining the object described are caps *a*, of platinum, attached to the bulb at the places where the conducting-wires enter it. Each cap is attached to the bulb by means of the fusion of the glass around the rim of the cap. The conducting-wires pass through or into the caps, and the junction of the wires and caps is secured air-tight by soldering, or, where the wire does not pass through the cap, but into it, soldering is not essential. A firm contact of the conducting-wires with the interior of the caps is in that case sufficient. The forms of cap I prefer to use are shown in the annexed drawings, figures 1 and 2.

(Here follow diagrams marked pp. 4125 & 4126.)

Fig. 1 shows a section, through its axis, of the kind of cap, *a*, I use when the wire passes through it, and is soldered into it. Fig. 2 shows a section, through its axis, of the kind of cap, *a*, I use when the wire only enters the inside of the cap, but does not pass through it.

The size and figure of the cap *a* may be varied to some extent without detriment to the object in view, and I therefore do not limit myself strictly to the exact size and form indicated by the drawings.

The second part of my invention has for its object to prevent the rupture of the carbon within the exhausted glass bulb, as the results of its unequal contraction.

I have found that when the carbon employed within the lamp is formed of a horseshoe-shaped plate, produced by cutting out the horseshoe-shaped piece from a sheet of card-board, and afterward

carbonizing it by heat, the horseshoe-shaped carbon-plate so produced is liable to become distorted and ultimately to break in consequence of the unequal contraction caused by the unequal heating of the inner and outer portions of the arch during the use of the lamp.

The defect above described I remedy by forming the carbon to be made incandescent of a strip of card-board, paper, or parchment-paper, *b*, bent into the form of an arch, hoop, or loop, the front view, Fig. 3, of such an arch, hoop, or loop showing its section or thickness, and the side view, Fig. 4, its width.

Where the paper is cut out in the shape of a horseshoe or an arch the measurement at the inner side of the arch is less than that around the outer side of the arch; hence the inner portion offers less resistance to the current than the outside, and becomes the most highly heated.

In my improvement the straight strip offers a uniform resistance to the current, and this resistance is the same and the temperature uniform when the strip of paper is bent to the required form. The strip of card-board, paper, or parchment-paper *b*, bent as aforesaid, I subject to a white heat in a closed vessel of a suitable material, such as fire-clay containing powdered charcoal or other suitable air-excluding powder. I mount one or more of the curved carbon strips, formed as above described, within a glass bulb by clipping the ends of the said curved carbon strips between forceps *c*, of platinum, or an alloy of platinum and iridium, attached to the conducting-wires, which pass through or into the caps, as before described.

The carbon arch and the caps are shown in position in a lamp in Figs. 5 and 6, in which Fig. 5 is a front view, and Fig. 6 a side view, of the carbon, the glass bulb being shown in section.

I guard against the destruction of a lamp in consequence of the accidental rupture of the carbon within it by employing two or more pieces of carbon, *b*, in each lamp.

The multiple carbon arches I clip together by their ends
4128 by means of platinum forceps *c*, before mentioned. I spread
out the arches in the manner indicated in Figs. 7 and 8, in which Fig. 7 is a front view, and Fig. 8 a side view, of the carbons as arranged in a lamp, the glass bulb being shown in section.

The third part of my invention has for its object the prevention of the evolution of gas occluded by the conducting-wires within the lamps and the prevention of leakage through the platinum caps; and these objects I accomplish by coating the conducting-wires and caps with glass or enamel.

The parchment-paper, which I prefer to use, produces a much stronger and more elastic carbon than the paper or bristol-board heretofore employed, and offers a more uniform resistance to the current.

I claim as my invention—

1. The combination, with an electric lamp, of platinum caps in the glass where the conductors are applied, substantially as specified.

2. In an incandescent electric lamp, a carbon formed from a straight strip of card-board, paper, or parchment-paper, and bent to the form of an arch, hoop, or loop, and carbonized by heat while in a bent condition, substantially as set forth.

3. A carbon for an electric lamp made of the carbonized parchment-paper.

4. In an electric lamp, the internal wires and caps coated with glass or enamel.

Signed by me this 15th day of March, A. D. 1880.

JOSEPH WILSON SWAN.

4130 UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company, of New York, N. Y.

Carbon for Electric Lamps.

Specification forming part of Letters Patent No. 251,540, dated December 27, 1881. Application filed August 6, 1880. (No model.)

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful improvement in carbons for electric lamps; and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawings, and to the letters of reference marked thereon:

In incandescent electric lighting I prefer to use for the incandescing conductor a small slip or filament of carbon bent into a curve, now generally designated the "horseshoe" carbon. Great success has attended the use of such carbons made from a naturally fibrous material capable of carbonization—for instance, wood formed into proper shape and then carbonized. I have found, however, that the best results are attained with the use of those materials which are fibrous, and wherein the fibers making up the mass of material lie naturally parallel, so that the individual fibers extend from end to end, increasing its strength and obviating danger of breakage from cross or oblique grain.

To produce the best results in giving light it is essential that the carbons should be of uniform size throughout the portion that is rendered incandescent, in order that radiating surface and resistance be regular and uniform, insuring even heating and incandescence.

The object of this invention, therefore, is to produce a small slip or filament for the carbon having parallel fibers and of uniform size; and to this end it consists in a carbon made of the materials and in the way more particularly hereinafter described and claimed.

I have found that for the purposes of the carbon filament cane bamboo is eminently suited, it having long parallel fibers, and with a minimum of cementing or other foreign matters. The cane bamboo is cut into strips, from which the hard glossy or silicious exterior and the pithy interior have been before removed, or from which they are now removed. Each strip is then cut or shaved by proper devices or machinery until its body, or part intended for light-giving, is reduced to the desired form and size, the ends being formed into enlargements, affording a good bearing or surface for uniting the finished carbons to metallic conductors. It is preferable that these enlargements of the ends be formed entirely upon side of the finished slip which forms the blank for carbonization, instead of upon both sides. This construction enables the blank, when placed on edge in the carbonizer, to more readily move therein as it is contracted in the process of carbonization. As the material shrinks in the process of carbonization, the finished carbon being smaller than the blank, allowance is to be made therefor in preparing the blanks, and they should be made proportionately larger than the size desired for the finished carbon. One or a number of blanks thus prepared are then placed in a suitable carbonizing oven or flask and thoroughly carbonized.

(Here follows diagram marked p. 4129.)

In the drawings, figure 1 represents a blank made from cane bamboo, ready for carbonization, having enlarged or clamping ends *s s* formed on one edge only, while in these enlarged or clamping ends are the slots *i i*, by which the slips may be secured in the carbonizer, and which also may form the holes through which pass the screws or clamps, if clamps be used for securing the finished carbon to leading-in wires. Fig. 2 shows in perspective a finished carbon made from the blank shown in Fig. 1.

What I claim is—

1. A slip or filament for forming on carbonization the incandescing conductor of an electric light, made of bamboo or similar fiber, substantially as set forth.

2. An incandescing carbon conductor for electric lights, made from cane bamboo or similar fiber, substantially as set forth.

This specification signed and witnessed this 28th day of July, 1880.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company, of New York, N. Y.

Electric Distribution and Translation System.

Specification forming part of Letters Patent No. 264,642, dated September 19, 1882.

Application filed August 9, 1880. (No model.) Patented in England September 24, 1880, No. 3880; in Canada November 15, 1880, No. 11997; in Italy November 19, 1880; in Belgium November 30, 1880, No. 53018; in France January 3, 1881, No. 139,588; in Victoria January 4, 1881, No. 2944; in Austria February 3, 1881; in New South Wales March 7, 1881; in New Zealand March 7, 1881, No. 512; in Queensland March 9, 1881; in Spain April 2, 1881, and in India July 20, 1881, No. 528.

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful electric distribution and translation system, (case No. 236;) and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawings, and to the letters of reference marked thereon.

This invention relates to a method of equalizing the tension or "pressure" of the current through an entire system of electric lighting or other translation of electric force, preventing what is ordinarily known as a "drop" in those portions of the system the more remote from the central station, and also to other features in systems for the utilization of electricity, as hereinafter explained.

As is well known from patents already granted me and prior applications pending, I use in my system an electric light formed of a continuous incandescing conductor, large numbers of which are grouped into one system, supplied and regulated from a central station, main conductors leading from and to the central station, each lamp or translating device being in a derived circuit to the main conductors, the entire system being what is known as a "multiple-arc" system. From a central station the main conductors may proceed, and it is intended that they should, to a great distance and supply a large number of translating devices. In such cases there is inevitably a difference in tension between various parts of the circuit, due to the resistance of the main conductors. This may be partially remedied by making the conductors very large near or at the station, gradually decreasing their size or conducting capacity; but such plan only lessens slightly the ratio of fall. To obviate the difficulty I provide feeding-conductors, which extend from the generator or generators to the main conductors of the lamp or consumption circuit or circuits, such feeding-conductors not having any translating devices connected therewith, and being connected with the main conductors of the consumption circuit or circuits at the center, ends, or other points on such main conductors. From a central station several sets of such feeding-conductors may run, each set feeding into its own lamp or consumption-circuit or all the sets feeding into a connected system of lamp or consumption circuits. It will be seen that the drop upon the feeding-conductors has no effect upon the relative candle-power of the lamps of the system, the relative candle-power of the lamps being affected only by the drop upon the main conductors of the consumption circuit or circuits between the end of a set of feeding-conductors and points most distant from any feeding-conductors. In order to maintain practically the same candle-power throughout the system, the main conductors of the consumption circuit or circuits should be so proportioned that the drop in tension upon them shall not exceed a definite small limit—for example, five per cent. This drop will make a difference of less than a candle-power in all the sixteen-candle-power lamps of the system, which difference is not perceptible to the eye. Upon the feeding-conductors, however, any loss can be made. This loss will be varied according to localities and the relative cost of copper for conducting purposes and horse-power for generation. This loss upon the feeding-conductors in large and extended systems will generally be greater than upon the main conductors of the consumption circuit or circuits. It may be, for example, about fifteen per cent.; but circumstances might make it desirable to diminish the loss upon the feeding-conductors down even as low as that upon the main conductors of the consumption circuit or circuits, or to increase the loss upon the feeders to more than fifteen per cent.

In this connection I wish to state that I am aware of the French patent of Khotinsky, No. 107,307, granted March 19, 1875.

When it is desired to use a few lamps near the central station they may be placed upon a direct circuit therefrom, with resistance at the commencement or home end of the circuit sufficient to then reduce the tension of the current in such circuit so that it shall
4135 only be equal to that in the more distant circuits, and one
or more of such circuits may be combined with the circuits before described. When large buildings or blocks of buildings using many lamps are to be supplied, it may be desirable to lay therefor separate feeders insulated from each other.

Where several central stations are used in a city, each having feeding-conductors leading to lamp-circuit conductors of the description before noted, it may be advisable to connect the feeding-circuits of all the stations, equalizing the tension or pressure throughout the entire system of the place where the central stations are located.

In the drawings are given diagrammatic representations of circuits, which will be more fully hereinafter described.

By Richd. N. Dyer.
Attorney.

Figure 1 illustrates a plan wherein the conductors are made larger at their home ends, gradually tapering to the outer end of the system. Where such plan is used it is preferable to make the conductor a compound one, composed of several single wires of different lengths, one or two of which extend the whole length of the conductor, others ending at various points, as shown in Fig. 1^b. These wires are not insulated, but merely grouped in a bunch, which have transverse fastenings at intervals, or which may be fastened together by branch conductors passing around where connections are formed, as shown in Fig, 1^a. It is preferable to form all conductors which vary in size, decreasing from some point in this manner, and it is to be understood in subsequent descriptions that all such conductors are so made.

In Fig. 2 feeding-conductors 1 2 lead from central station C S, connecting with the lamp-circuit 3 4 at about its center, the conductors of the lamp-circuit being largest at that point, and also of slightly larger capacity at that point than the feeding-conductors. By this arrangement most of the fall of pressure or drop in tension takes place in the feeding-circuit, so that it cannot affect any lamps, while the drop in the lamp-circuit is reduced very low, as before explained, the drop from the center of the lamp-circuit to either terminal being only about one-fourth what the drop would be from *y* to *z* if either end were connected directly to the central station. Any desired number of lamp-circuits may be so arranged, each having its proper feeding-conductors, two so arranged being shown in Fig. 3.

In some instances where it is desired to use a few lamps near the station they may be placed directly upon main conductors, and combined with the circuits shown in Figs. 2 and 3, as shown in Fig. 4, where feeders 5 6 connect with lamp-circuit 9 10, arranged as in Figs. 2 and 3, while circuit 1 2, connected directly to C S, has a few lamps upon it, in which case resistances R R should be used therein to lessen the tension of the current in 1 2 to the same extent as it is lessened by the larger conductors 5 6. With such arrangement may also be combined an ordinary terminal circuit containing a few lamps, such as the circuit 13 14 in Fig. 5.

In Fig. 6 is shown direct or main feeding circuits 1 2 and 5 6 with lamp-circuits 3 4 and 9 10 with branch feeders 7 8, 15 16, and 21 22 leading into side streets, supplying lamp-circuits 17 18, 19 20, 23 24, and 25 26, the branch feeders being derived circuits from the main feeders, all constituting a multiple-arc system.

In Fig. 7 feeding-mains 1 2 connect to the center of the lamp-circuit 3 4, while feeders 5 6, leading to a greater distance and to a circuit when comparatively few lamps are required, connects to the end of lamp-circuit 9 10, whose conductors gradually taper from the point of connection. This arrangement is sometimes desirable in sparsely-settled localities, as involving economy in the laying of conductors.

In Fig. 8 is shown feeding-conductors 1 2, from which lead house-feeders *a b*, which connect to lamp-circuits *a′ b′*, which are of same description as circuit 3 4, Fig. 2.

Fig. 9 shows a series of houses or buildings, *c d e f*, to each of which leads a feeding-circuit of insulated conductor, the lamp-circuit of each house being thereby put in direct connection with the central station C S, the tension of the current in any one lamp-circuit not being effected by the others.

In Fig. 10 are two blocks of buildings, A and B, composed each of several houses, *h h h*, separate feeding-circuits 1 2 and 3 4 leading to branch feeding circuits, from which lamp-circuits lead into each house, each house or lamp-circuit being provided with its own connection and meter.

In the arrangements shown in Figs. 8, 9, and 10 the greatest portion of the fall or drop occurs in the conductors leading to the house or block lamp-circuits, the tension or pressure in the branches leading into the houses being maintained practically uniform thereby in each lamp-circuit.

Fig. 11 shows a series of central stations, C S, from each of which lead main feeding-circuits M, which may be of any desired number, each connecting to and feeding into a lamp-circuit, *l c*. The mains of all the stations are connected by conductors *n n n*, so that all the stations are electrically connected into one general system, whereby the pressure throughout the entire system is equalized.

In Fig. 12 the lamp-circuit L C is fed by a number of feeding-circuits, connecting thereto on opposite sides, alternately 1 2, 3 4, and 5 6, forming three feeding-circuits, by which arrangement a comparatively uniform force or pressure may be maintained throughout the entire system.

I do not claim broadly a conductor tapering from the source of energy, as such, *per se*, is old; but I do claim, as hereinafter set forth, my particular way of forming such a conductor.

What I claim is—

4136 1. A consumption-circuit, in the main conductors of which the drop in tension is not sufficient to vary practically the candle-power of the lamps connected therewith, in combination with feeding-conductors connecting the consumption-circuit with the source of electrical energy, and having no translating devices connected therewith, the drop in tension upon such feeding-conductors not affecting the relative candle-power of the lamps of the consumption-circuit, substantially as set forth.

2. A consumption-circuit in the main conductors of which there is a definite small drop in tension not sufficient to vary practically the candle-power of the lamps connected therewith, in combination with feeding-conductors connecting the consumption-circuit with the source of electrical energy, and having no translating devices connected therewith, the loss upon such feeding-conductors being greater than upon the main conductors of the consumption-circuit, substantially as set forth.

3. The combination of a consumption-circuit, in the main conductors of which the drop in tension is not sufficient to vary practically the candle-power of the lamps connected therewith, with a feeding-circuit having no translating devices, and extending from

the source of electrical energy to the center of the consumption-circuit, substantially as set forth.

4. The combination of two or more central stations having feeding-conductors, and consumption circuits supplied by such feeding-conductors, as described, of connections between the conductors of the central stations, substantially as and for the purposes set forth.

5. The combination, in one system, of a main circuit connected directly to a source of energy, and containing translating devices, and provided with resistances for lessening the tension or pressure of the current to that of the average of the system, a circuit not directly connected to the source of energy containing translating devices, and a feeding-circuit connecting the latter circuit with the source of energy, substantially as set forth.

6. The combination of a number of uninsulated wires of different lengths grouped together and fastened at intervals, forming a gradually-tapering conductor, substantially as set forth.

This specification signed and witnessed this 4th day of August 1880.

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, of Menlo Park, New Jersey, assignor to the Edison Electric Light Company, of New York, N. Y.

Electric Distribution System.

Specification forming part of Letters Patent No. 266,793, dated October 31, 1882. Application filed December 9, 1881. (No model.)

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful improvement in electrical distribution systems, (case No. 361;) and I do hereby declare that the following is a full and exact description of the same, reference being had to the accompanying drawings, and to the letters of reference marked thereon.

In a system of electric lighting in which a town or village or a portion thereof is supplied from one central station it may sometimes occur that the district supplied is irregular in shape, and that in some parts of the district more lights may be used, and consequently more electricity required, than in others.

The object of this invention is to so arrange the system of conductors supplying the district that the supply in the various localities of the district will be proportioned to the demand.

In a prior application I have set forth the manner in which I usually prefer to arrange my conductors in cases where about the same supply is required all over the district, viz: Along each face of each block in the district are laid two conductors—one "positive," the other "negative"—and at every street-corner where the conductors intersect each other all the positive conductors are connected together and all the negative—that is, wherever two conductors of the same name cross each other they are connected together—and feeding-conductors connect with these street-mains at certain definite and regularly-arranged points, so that a constant amount of electricity is supplied in all parts of the district in a uniform manner; but where, as explained above, the district is irregular in shape and some parts of it require more current than others this arrangement is modified as follows: By estimating the number of lamps or other translating devices used in the entire district and the proportion used in various parts thereof, I am enabled to discover what may be termed the "centers of consumption"—that is, the points in the neighborhood of which or around which a certain amount of electricity is consumed.

In parts of the district which are thickly settled and contain a good many consumers of electricity the center of consumption would be the center of a very small space, while in sparsely-inhabited localities, where few lamps are used, the space surrounding the center of consumption would be larger. The district might thus be considered as divided into irregularly-

BY Dyer & Wilber

ATTORNEYS.

shaped sub-districts, each containing about the same number of lamps, and each consuming approximately the same amount of energy. To each of these centers of consumption is run from the central station a "feeding-circuit," consisting of a positive and a negative conductor, each of which is connected at the proper point to a similar conductor of the main system. As stated above, all the positive and all the negative main conductors are connected together wherever they intersect. I sometimes find it desirable to connect them also at other points by running cross-connections across the street at various places along the faces of the blocks.

The feeding-conductors are preferably of the form set forth in my prior application, (serial No. 31825,) with the exception that small additional wires are laid in the tubes, which form additional circuits, each of which runs from a center of consumption back to the central station, where it passes through an electro-dynamometer or other suitable device for indicating electric pressure, and thence returns again to the center of consumption, so that the amount of energy used in each feeding-circuit or the electrical potential at center of consumption is indicated, and adjustable resistances are placed in each feeding-circuit, so that according to the indications of the electro-dynamometer more or less current may be supplied to the circuit. The main conductors of the consumption-circuit are made of such size that the drop in electro-motive force upon them will not be sufficient to vary practically the candle-power of the lamps, while upon the feeding-conductors any drop may be provided for without affecting the relative candle-power of the lamps of the consumption-circuit, such feeding-conductors having no translating devices connected therewith. The loss upon the feeding-conductors 4139 is preferably greater than that upon the main conductors of the consumption-circuit, but will be varied in different localities according to the relative cost of copper for conducting purposes and horse-power for generation. The electro-dynamometer used is preferably that of Weber, a large resistance—say 10,000 ohms—being placed in circuit with the instrument, as is well understood, so that the instrument will vary with the variations in tension, and will practically indicate the electro-motive force of the current.

(Here follows diagram marked p. 4137.)

In the accompanying drawings, figure 1 is a diagram of a district, showing the system of mains and feeding-circuits; Fig. 2, a diagram showing a part of the district, with a portion of the apparatus used at the central station; and Fig. 3 is a cross-section of one of the underground tubes containing the conductors of a feeding-circuit.

A, Fig. 1, represents a central station; N and P, respectively, the negative and positive poles of batteries of electric generators situated in the station. B B′ B″ are blocks which compose the district or part of it. The blocks B′ B″ may be taken as types of all the others. In each of the streets surrounding these blocks are laid the main conductors *p n*, *p* representing positive and *n* negative conductors.

Wherever conductors of the same name cross each other they are run into a junction-box and connected, and additional connections may also be made between them by cross-conductors *n' p'*, placed across the street at various points along the faces of the blocks.

The centers of consumption are, as before explained, various irregularly-located points at different distances from the source of supply, A, such as the points C D E F. To these points are run the feeding-circuits, each consisting of a positive conductor, *p''*, and a negative conductor, *n''*. The conductors *p''* all run from positive poles P of the generators and the conductors *n''* from negative poles N. By these feeding-circuits electricity is supplied to the different groups of lamps, each of which surrounds a center of consumption.

In Fig. 3, *n'' p''* are the feeding-conductors, surrounded by insulating-washer G, which separates them from an inclosing metal tube H. *c c'* are small wires, which also pass through the tube H.

Fig. 2 illustrates the manner in which the conductors surrounding any block B of the district are arranged.

I I represent a battery of electric generators, N P being respectively its negative and positive poles, from which run the feeding-conductors *n'' p''* to the centers of consumption of the block, where they are connected to the street conductors *n p* by means of the junction-boxes described in a prior application.

For convenience in the drawings, the wires *c c'*, which are inclosed in the same tube with the conductors *n'' p''*, are shown separated from these conductors in Fig. 2. These wires *c c'* form an auxiliary circuit to each feeding-circuit, passing through electro-dynamometers *b b* or other suitable devices for indicating electric pressure at the central station, which by this means indicates the electrical potential at the centers of consumption.

d d are adjustable resistances, placed in the feeding-circuits, by means of which more or less current may be made to pass through such circuits, according to the indications of the electro-dynamometers.

What I claim as my invention is—

1. In a system of electrical distribution, the intersecting and connected positive conductors and the intersecting and connected negative conductors, forming the main conductors of the consumption-circuit, upon which the drop in electro-motive force is not sufficient to vary practically the candle-power of the lamps, in combination with a central station and feeding-conductors having no translating devices connected therewith, and extending from the source of electrical energy at the central station to the main conductors of the consumption-circuit, said feeding-conductors being connected with such main conductors of the consumption-circuit at or near centers of consumption, substantially as set forth.

2. The combination, with a feeding-circuit of an electrical distribution system, of an auxiliary circuit composed of smaller con-

ductors connected at its terminals with the terminals of the feeding-circuit, and containing a suitable device for indicating electric tension, so that the electro-motive force of the current in the main circuit is indicated, substantially as set forth.

3. The combination of the conductors forming a circuit of an electrical distribution system, placed in an enclosing tube, of smaller conductors in the same tube, having their terminals connected with those of the main conductors, and forming a circuit in which is placed a suitable device for indicating electric tension, substantially as and for the purpose set forth.

4. In a system of electrical distribution, the combination of the intersecting and connected positive conductors and the intersecting and connected negative conductors, forming the main conductors of the consumption-circuit, with cross-connections connecting the conductors of the same polarity together between the points of intersection, a central station, and feeding conductors having no translating devices connected therewith, and extending from the source of electrical energy at the central station to the main conductors of the consumption circuit at or near centers of consumption, substantially as set forth.

5. In a system of electrical distribution, the intersecting and connected positive conductors and the intersecting and connected negative conductors, forming the main conductors of the consumption-circuit, in combination with a central station, feeding-conductors 4140 extending from the central station to the consumption circuit, and having no translating devices connected therewith, and means located in each feeding-circuit for regulating the tension of the current supplied thereby to the consumption-circuit, substantially as set forth.

6. In a system of electrical distribution, the intersecting and connected positive conductors and the intersecting and connected negative conductors, forming the main conductors of the consumption-circuit, in combination with a central station, feeding-conductors extending from the central station to the consumption-circuit, and having no translating devices connected therewith, an auxiliary circuit extending to the outer end of each feeding-circuit and containing a device for indicating electro-motive force, and an adjustable resistance in each feeding-circuit, substantially as set forth.

This specification signed and witnessed this 25th day of October, 1881.

H. W. SEELY.
RICH'D N. DYER.

4145 UNITED STATES PATENT OFFICE.

Thomas A. Edison, of Menlo Park, New Jersey, assignor, by mesne assignments, to the Edison Electric Light Company of New York, N. Y.

System of Electrical Distribution.

Specification forming part of Letters Patent No. 369,280, dated August 30, 1887.

Application filed February 5, 1880. Serial No. 2282. Patented in England February 11, 1880, No. 602; in Italy May 10, 1880, No. 11809; in Belgium May 15, 1880, No. 51329; in France July 5, 1880, No. 136,399; in Canada July 21, 1880, No. 11527, and in Austria-Hungary October 5, 1880, No. 30–1837.

To all whom it may concern:

Be it known that I, Thomas A. Edison, of Menlo Park, in the State of New Jersey, United States of America, have made certain new and useful improvements in furnishing light and power from electricity, of which the following is a specification.

The object of this invention is to arrange a system for the generation, supply, and consumption, for either light or power, or both, of electricity, that all the operations connected therewith requiring special care, attention, or knowledge of the art shall be performed for many consumers at central stations, leaving the consumers only the work of turning off or on the supply, as may be desired—in other words, to so contrive means and methods that electricity may be supplied for consumption in a manner analogous to the systems for the supply of gas and water without requiring any greater care or technical knowledge on the part of the consumer than does the use of gas or water, in order that economy, reliability, and safety may be insured.

In carrying the invention into effect, a city, town, village, or locality may form one district, or, if the extent of territory makes it desirable, may be divided into several districts. In each district I provide a central station, at which are grouped a suitable prime motor or several motors, dependent upon the amount to be supplied, generators or means for converting the prime motive force into electricity, and means for determining and regulating the amount of electricity generated and supplied, in order that a constant pressure of electricity (so to speak) may be kept up. The prime motors are any suitable engines, steam or water, and one or a series of two or more is provided, as may be necessary, each of which is provided with its own system of shafting and belting, driving a number of magneto-electric machines, the number actuated by one prime motor being hereinafter termed a "battery."

It is to be noted, as is also shown in previous applications for patents made by me, that I make my field-of-force magnets exceedingly long and of an extremely large mass of metal in proportion to the mass of metal in the revolving armature carrying the generating-coils. The effect of this is to give to the generators field-magnets of great strength, so that currents of the desired high electromotive force can be generated in armatures of low resistance, and the waste of energy in the form of heat in such armatures will be reduced to the minimum. I desire to avoid also the use of generators having the coils of their field-magnets in series with their generating-coils, since this, besides being a defective arrangement with respect to regulation, also increases the internal resistance of the machines, and results in an objectionable waste of energy; hence I prefer to keep the coils of the field-of-force magnets and the generating-coils separate, and that one machine in each battery (which machine may be termed the "battery field-of-force generator") be used to supply the requisite energy to the field-of-force magnets of the other machines in such battery, (which may be termed the "supply-generators.") The coils of the field-of-force magnets are connected as a series or in a multiple arc in one circuit, while the generating-coils of the supply-generators of each battery are all connected in a multiple arc to the main conductors. This arrangement, it is seen, gives great economy, as the per cent. of the entire current generated in each battery absorbed in keeping up the magnetic maximum in the field-of-force magnets when it is furnished by one special machine of the battery, the number given it to feed being properly calculated, being less than when a portion of the current generated in each machine is absorbed in its own field-of-force magnets.

Where a single battery of machines is used, it is preferable, in view of what has been hereinbefore stated, that the current for the coils of the field-of-force magnets of the field-of-force generator of the battery be supplied by a small galvanic battery; but if more than 4146 one battery of machines be used the field-of-force generators of all the batteries are fed from one or more prime field-of-force generators connected in a multiple arc or in a series, the field-of-force magnets of the prime field-of-force generator or generators used being kept magnetically saturated by a weak galvanic-battery current, as before set forth. For instance, a weak galvanic current supplies the field-current necessary for one prime field-of-force generator, which in turn feeds the field-of-force magnets of the field-of-force generators of the batteries of twenty or thirty machines, the ultimate effect in the generation of current depending upon (as one important factor) the tension of the galvanic current sent through the field-of-force coils of the prime field-of-force generator. This prime field-of-force generator may, however, be a dynamo-electric machine instead of a magneto-machine, its field of force being kept up by the current generated in the machine instead of by a galvanic current.

At the central station all the supply-generating coils or batteries thereof are connected to conductors on the multiple-arc system, and from these conductors at the station main conductors (which for conveience may be called simply the "mains") connected thereto, also on the multiple-arc system, lead in any and all desired directions for conveying the energy to the points where work, either by translation into light or motive power, is to be done. All of such conductors from the generators at the station to the lamps are made in pairs—one from the outgoing current and the other for the returning current of electricity, the circuits throughout the system being complete or round metallic circuits, the conductors of which are well insulated from each other and from the earth. The use of the earth for one-half of the circuit would largely increase the difficulties arising from the grounding of the conductors or the crossing of the conductors among themselves or with the conductors of other circuits to such an extent that a system so constructed would be impracticable.

In order to give a better understanding of the method of regulating what, for convenience, may be called the "pressure" of the current through the entire system, I will here state that all the devices for translation of electricity into work are arranged on the multiple-arc system, each device being in its own derived circuit, the effect being, in substance, to give each a circuit from the generating source independent of the circuit of all the other devices. As a resultant, it follows that the greater the number of translating devices brought into circuit the less the total resistance of the circuit. For instance, I prefer that my lamps should each be of about one hundred ohms resistance. Then, if one lamp only be in circuit, there is a resistance of one hundred ohms. If another lamp be put in circuit, two circuits, each of one hundred ohms, are provided for the current, making the net total resistance to the current fifty ohms, although the resistance in each derived circuit remains unchanged. This effect is ordinarily opposite to the effect produced by the addition of lamps when they are connected in an ordinary straight circuit, each one then adding to the resistance of the circuit.

The bringing into operation successively of numbers of the devices, and thereby making more paths or circuits for the currents, does not appreciably lessen the pressure or diminish the effect upon the devices in use, the active forces at the central station—viz., prime field-of-force generators and motive power—remaining unchanged until the net resistance of the devices in circuit exterior to the battery of machines is so diminished as to approach in a degree the resistance of the battery and main conductors, it being remembered that as the machines of a battery are connected in multiple arc the net internal resistance of a battery is as many times less than one machine as there are machines in the battery.

To avoid any appreciable variations and insure uniformity, it is essential that any lessening of pressure be immediately indicated, in order that just sufficient energy be generated and sent out to keep up an equal flow through the circuit of each translating device—that is, that the pressure be kept up uniform, whether more or less translating devices be in circuit. This is attained by providing at the central station means for constantly indicating the pressure and for regulating the production if appreciable variation be indicated. At each central station test lights are arranged, so that an approximate visual test of the effect of pressure upon the circuit of any translating devices in use may be shown. From what has been said, it is evident that as more or less translating devices are brought into circuit the total resistance of the circuit, or all the circuits thereof, to the flow of all the current generated varies. To indicate this electro-dynamometers, galvanometers, or electrometers are placed across the main conductor at the central station, or by return-wire at any point in the circuit, with a zero-mark placed to correspond with the deflection consequent upon the maintenance of the proper amount of pressure. It may be advisable (and I have so done) to place at the central station a series of standard Daniell batteries, connected by a switch-circuit to the galvanometors or electro-dynamometers, in order that they may be frequently tested for any inaccuracy occurring from any cause whatever. By these means any error whatever therein is readily detected.

To correct variations in the pressure various means may be employed. Each supply-generator may be connected into the circuit
through a switch, and each series may be likewise so connected
4147 so that the current of one or more of a series, or one or more
entire series, may be cut out or thrown into the circuit, or
each machine may be arranged so as to be disconnected from the prime motor; or when needed, the prime motor of an entire series may be disconnected. The plan I prefer, howerer, is to arrange in connection with the circuit of the battery feeding the field-of-force magnets of the prime field-of-force generator before referred to a series of resistances, so that the energy of the battery-current may be varied, this variation causing in turn a variation in the current induced in the prime field-of-force generator and in all the generators directly or indirectly controlled thereby. Where a dynamo-machine is used these resistances are to be used in the same manner in connection with the circuit, including the coils around the field-magnets. For distribuing the current thus generated and regulated at the central stations I prefer to use conductors within insulated pipes or tubing, made water-tight and buried beneath the earth, provisions being made at suitable intervals for house or side connections, as shown in a prior application of mine. While this plan is preferable for many reasons, it is evident that conductors may be carried in the air or over house-tops.

While only one pair of conductors may be laid on each street, I prefer, especially where streets are wide, to lay a pair of conductors along each side of the street, near the curb. At proper intervals street-lamps may be connected thereto by derived circuits. From main conductors on principal streets subsidiary main conductors are laid through side streets. From the street conductors, wherever desired, derived circuits are led into houses, one of the conductors passing through a suitable meter, preferably one which measures the amount of electricity passing through, as shown in a prior application of mine for a patent.

In the house each translating device is placed in a derived circuit, the entire system of means for generation, conduction, and translation being one great multiple-arc system with complete or round metallic circuits. The translating devices in each house may be either for light or power, or both. For light the electric lamp consisting of an incandescing material hermetically sealed in glass (shown in other applications filed by me) is preferred. This lamp is made of a high resistance in comparison with that of any electric lamps which, to my knowledge, have been proposed.

In lights heretofore proposed the endeavor seems to have been to lessen the resistance of the carbon, none having been suggested of higher resistance than, say, ten ohms; but I have discovered that a very much higher resistance—say one hundred ohms—must be used, in order that a number may be economically and successfully used in a system.

The motors used should be so constructed that each, with a constant flow or pressure of current, will give the exact power required. This requires that each motor should be wound with finer or coarser wire and into more or less convolutions, which determine the maximum effect of the motor. In addition, as the motors may be run with variable loads or amounts of work to perform, and as irregularity of speed would be a consequent thereof, it would be preferable to provide each motor with a governor which an excessive speed would operate to break the circuit of the motor or to otherwise control it. A preferable form of governor therefore will form the subject-matter of an application for a patent to be filed by me.

A system arranged as thus described provides for all the conditions precedent to an economical and reliable utilization of electricity as a lighting or motive-power agent.

As within certain ascertainable limits, the greater the horse-power of an engine the less the proportionate cost per horse-power. By consolidating at one station the prime motive force necessary to the generation of a supply for many consumers a great economy as to production occurs.

As ordinarily proposed, each electric light requires its own regulator, which usually is either thermostatic or magnetic, breaking the circuit or bringing in resistance—in any case making a cumbrous lamp, requiring delicate management and constant attention. By regulating at the central station entirely, I am enabled to use a small separate lamp, which may be used with the exercise of no more than ordinary care or attention. The distribution is so provided for that tampering therewith is guarded against and that connections from the mains to localities of translation are readily made.

The means for measuring insure accurateness in furnishing a basis for equitable charges for the amount used by any particular consumer.

In the drawings accompanying and forming part of this specification an arrangement of means is shown for carrying my invention into effect, although it is to be particularly noted that the invention is not dependent upon the specific means and their arrangement noted and shown, but that they may be varied without departing from the spirit of my invention. The drawings illustrate, however, what I now consider the more preferable means and arrangements.

Inventor:

T. A. Edison per
Dyer & Wilber
Attys.

In these drawings, figure 1 is a plan view of a central station. Fig. 2 is a modification of Fig. 1. Fig. 3 is a plan view illustrating the street-mains and house-connections with translating devices properly introduced. Fig. 4 is a plan showing a locality divided into four districts.

In Fig. 1 three batteries of generation, C C' C^2, are shown, which number may be increased or diminished, as circumstances may demand. One generator, *c*, of each battery is used to generate the current feeding the field-of-force magnets of the other machines
4148 in its battery, the circuit from such field-generator through
the field-of-force coils in each battery being shown by the broken lines 2 2 2. For actuating the rotating parts an engine, D, is used with each battery, connected by belt *d* to line of shafting E, from which belts *e* pass to the generator. The coils of each battery in which currents are generated are connected, as in C' and C^2, in multiple arc to conductors 3 3 3 3, which in turn are connected in multiple arc to the main conductors 6 6, from which lead in multiple arc the street conductors or mains 7 7, or, as shown in part of battery C, each machine may be directly connected in multiple arc to the station-conductors 6 6. F is the prime field-of-force generator, supplying the battery field-of-force generators *c c c*, its circuit being shown in broken lines 1 1. The field-of-force magnets of F are magnetized by a current from the galvanic battery G, in whose circuit is arranged the series of conductors H, provided with the cut-out K, by which more or less of the resistances are put in or out of the circuit feeding the field of F. This arrangement forms a very effective and simple method of regulating the production of current or the pressure at the central station, for the current generated by F being dependent upon the intensity of the magnetization of its field-of-force magnets, which in turn depends upon the current transmitted around the magnets by the battery G, as the resistance varies such current, it follows that by varying the resistance in the circuit of G the current generated by F varies, which in turn varies the current generated in *c c c*, which in turn varies the current generated in the supply-machines of the batteries, proportionate increase of current and rise of pressure in the latter following increase of current around the magnets of F, and vice versa. One or more test-lamps, T L, are placed at the central station in derived circuits to serve as a photometric test of the pressure in the lines. For more accurately indicating variations in the pressure, one or more electrometers, galvanometers, or electro-dynamometers, E D, are placed in derived circuits, with a scale-mark indicating the pressure determined on as the standard pressure to be maintained. By the proper use of these indicating devices and the regulating devices described, a uniform pressure may be readily and easily maintained through all the mains. It is preferable to connect all circuits from the generating-machines to the main conductors 6 6 through switches I I I, so that an entire battery or any portion thereof may be thrown in or out of circuit, as the draft upon the station may indicate. It is to be noted, also, that the belt and pulleys of each machine are to be arranged by any of the well-known plans, that

it may be disconnected from the motor when desired These means may be used, when desired, as means of regulation, the number of machines in operation being controlled thereby, while the effective force of each machine while in operation is controlled by the resistances. The engines may be of any desired pattern or power, the number of machines in any one battery being limited by the power of the engine.

In Fig. 2, *c c c* are the field-of-force generators of batteries not shown, while *c′* is the field-of-force generator of a battery, of which three supply-generators are shown, connected to station-conductors 6 6, as before explained. The prime field-of-force generator F′ is in this case a dynamo-electric machine instead of a magneto-electric machine, as shown in Fig. 1, all its coils being included in one circuit, 8 8, which passes around the field-of-force magnets of the battery-generators *c c c c c′*. The same principle of regulation is used, however, the resistances H and cut-out K therefor being arranged in connection with the circuit through F′, so as to cause variation in the tension of the current therein, as and with the result before explained. In this figure there is shown what may be used also in connection with the plan shown in Fig. 1—means of testing the electro-dynamometers E D or other indicating instrument used. From a standard Daniell battery, D B, a circuit, *t c*, may be formed around E D by means of the switch L, so that, when desired, the correctness of E D may be ascertained and any inaccuracies which might arise be guarded against.

In Fig. 3 the mains 7 7 are shown, leading from corresponding wires at central station (see Fig. 1) down each side of the street. At side streets conductors 12 12 branch off. The small circles *o* in this figure indicate electric lamps. For street-lighting they are placed, as shown, in derived circuits from the street-mains. From the mains derived circuits 9 9 lead into houses, in which are placed at some suitable spot the meters M, through which one of the house-conductors passes, and by which the amount of electricity supplied to the house is accurately determined. Upon these house-circuits are arranged lamps on the multiple-arc system in such number, position, and grouping as may be desired. In these circuits I also propose to introduce electromotors E M, for furnishing light motive power. From the motor a belt, *i*, leads to a line of shafting, *h*, and pulleys *a a*, for any needed distribution of the power; or the belt *i* may pass directly to a sewing or other machine, a separate motor being used for each power-driven machine. Where motors are desired, each, preferably, should be made of a power proportional to the maximum work to be done. While the electrical tension in each machine is regulated at the central station, yet if the maximum load or work be diminished at any particular motor its speed would necessarily be increased. It also might be desired at times to diminish the normal speed of the motor. In order, therefore, that some determinate speed may be maintained, irrespective of load or work, each motor should be furnished with a governor. For this
4149 purpose I prefer a governor invented by me, and to be the

subject of a separate application, which acts to break the circuit when a certain determinate speed is exceeded.

In Fig. 4 is shown a locality divided into four supply districts. Each is provided with its own central station, marked C. S. 1, C. S. 2, C. S. 3, and C. S. 4. From each proper mains, 77, lead out, as before described. At convenient points, however—say P P—connections between the mains of the systems may be made, the effect then being to merge the entire locality into one large district with four supply stations, the pressure through all being uniform and each station doing its own quota toward maintaining the pressure uniform. The use of four stations and districts in this diagram is arbitrary and for illustration only, as the number actually to be made in any one locality depends upon the needs of the locality.

It is to be noted that all the circuits from the generators to the lamps or other translating devices are complete or round metallic circuits, as before stated.

What I claim is—

1. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of a number of generators connected in multiple arc with such circuit, and consisting each of an armature revolving in a magnetic field, and a number of translating devices, also connected in multiple arc with said circuit, substantially as set forth.

2. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of a number of generators connected in multiple arc with such circuit, and consisting each of an armature of low resistance revolving in a magnetic field of great strength, and a number of translating devices, also connected in multiple arc with said circuit, substantially as set forth.

3. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of a number of generators connected in multiple arc with such circuit, and consisting each of an armature revolving in a magnetic field and having the coils of its field-of-force magnet and its generating-coils separate, (*i. e.*, not connected in series,) and a number of translating devices, also connected in multiple arc with said circuit, substantially as set forth.

4. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of a number of generators connected in multiple arc with such circuit, and consisting each of an armature revolving in a magnetic field, a number of translating devices, also connected in multiple arc with said circuit, and a regulator for regulating the supply of current to such circuit, substantially as set forth.

5. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of means for generating electricity connected with such circuit, and consisting of one or more dynamo or magneto electric machines, translating devices connected in multiple arc with said circuit, an indicator of the electric pressure upon such circuit, and a regulator under control of the operator for regulating the supply of current to such circuit, substantially as set forth.

6. In a system of electrical distribution, the combination, with a complete or round metallic circuit, of a number of generators connected in multiple arc with such circuit, and consisting each of an armature revolving in a magnetic field, translating devices connected in multiple arc with said circuit, an indicator of the electric pressure upon such circuit, and a regulator under control of the operator for regulating the supply of current to such circuit, substantially as set forth.

7. In a system for the generation and distribution of electricity for light or power through cities or towns or districts thereof, a central station whereat are combined a number of generators of electricity connected in multiple arc, and consisting each of an armature revolving in a magnetic field, an indicator of the electric pressure, and a regulator of the current generated, conductors forming complete or round metallic circuits leading from such station to distribute the current throughout the system, and translating devices connected in multiple arc with such conductors, substantially as set forth.

8. In a system for the generation and distribution of electricity for light or power through cities or towns or districts thereof, a central station whereat are combined a number or generators of electricity connected in multiple arc, and consisting each of an armature revolving in a magnetic field, an indicator of electric pressure, and a regulator of the current generated, conductors forming complete or round metallic circuits leading from such station to distribute the current throughout the system, translating devices connecting in multiple arc with such conductors, and meters at the houses for measuring the current supplied to such translating devices, substantially as set forth.

In testimony whereof I have hereunto affixed ny signature this 28th day of January, A. D. 1880.

Applying Motive Power to the Impulsion of Machinery, &c.

Pinkus' specification.

To all to whom these presents shall come, I, Henry Pinkus, late of Banton square, Coventry street, in the county of Middlesex, but now of No. 36 Maddox street, Regents street, in the said county of Middlesex, Esquire, send greeting:

Whereas her present most Excellent Majesty Queen Victoria, in and by her letters patent under the great seal of Great Britain, bearing date at Westminster, the twenty-fourth day of September, one thousand eight hundred and forty, for herself, her heirs, and successors, did give and grant unto me, the said Henry Pinkus, my

executors, administrators, and assigns, and every of them, by myself and themselves, or by my and their deputy or deputies, servants or agents, or such others as I, the said Henry Pinkus, my executors, administrators, or assigns, should at any time agree with, and no others, from time to time and at all times thereafter during the term of years therein unexpired, should and lawfully might make, use, exercise, and vend within England, Wales, and the town of Berwick-upon-Tweed, and also the colonies and plantations abroad, my invention for "improvements in the methods of applying motive power to the impelling of machinery, applicable, amongst other things, to impelling carriages on railways, on common roads or ways and through fields and vessels afloat, and in the methods of constructing the roads or ways on which carriages may be impelled or propelled," in which said letters patent is contained
4151 a proviso that I, the said Henry Pinkus, shall cause a particular description of the nature of my said invention, and in what manner the same is to be performed, to be enrolled in her said majesty's high court of chancery in England, with- six calendar months next and immediately after the date of the said in part recited letters patent as in and by the same, reference thereunto had, will more fully and at large appear.

Now know ye that, in compliance with the said proviso, I, the said Henry Pinkus, do hereby declare that my invention of improvements in the method of applying motive power to the impelling of machinery, applicable, amongst other things, to impelling carriages on railways, on common roads or ways and through fields and vessels afloat, and in the methods of constructing the roads or ways on which carriages may be impelled or propelled, consist- particularly in the methods of applying and using several seperate and distinct but well-known sources or means of acquiring motive power or powers, force or forces, some of which were specified and applied in my former patent for England, dated twenty-sixth August, one thousand eight hundred and thirty-nine, whereby and by means herein described I induce, transfer, or transmit, as herein described, the motive forces which I cause to be generated and which I apply to the different circumstances, things, and uses herein described, consisting partly in varying the methods or applications described in my said former specification, the variations and additions being—

First. The motive forces, or any or them, to effect propulsion on railways. I vary one of the said motive forces, to wit, what I term gaso-pneumatic in the following manner: That is to say, on a line of railway of the ordinary construction or any modification thereof I lay and continue along the whole length of such railway as series of common gas mains or pipes, 2 of any convenient diameter, say about five or six inches in diameter. These are laid, if on a double track, in a center line between the two tracks of railway at
4152 distances of about two miles along said line. I lead a bend or bends, a branch or branches, of any required length from said mains, and to these, where they occur, I connect and establish the gas-explosive apparatus or engine *g g*, or parts thereof, de-

scribed in my said former specification, being fixtures upon said line of railway, in the manner hereinbefore described, reference being had to the several drawings and figures hereinafter referred to, or in any similar way. From the engine or apparatus so to be constructed I transfer or transmit the power or force induced at each station along a line of said railway in opposite directions by the effect of the explosive mixtures of gasses and air, the former supplied through said mains from gasometer stations placed at convenient distances, say ten miles apart, along said railway, and thus I vary the method of applying said power described in my said former specification.

Secondly. To effect propulsion on canals. I also vary the method described in my said former specification in manner hereinafter described and referred to in the accompanying drawings and figures.

Thirdly. I effect a motive force or power by applying the aforesaid gaso-pneumatic principle to impelling machinery, to wit, the impelling engine described in my said former specification dated twenty-fifth day of Feb-uary, one thousand eight hundred and forty-one, being the gaso-pneumatic engine therein referred to, and apply the said gaso-pneumatic engine to another and different use by combining with it a method of communicating a source of motive force, to wit, gas, which I take up from the public mains or pipes when laid down in cities, towns, and other places for the purpose of supplying gas for lighting and by the combination of method and apparatus hereinafter described construct and apply the same to the purpose of a fire-engine.

Fourthly. I further vary the methods of effecting propulsion on said railways or said canals by one of said motive powers or forces,
to wit, steam power, in combination with the same or parts of
4153 the same, impelling machinery or apparatus in lieu of gaso-
pneumatic power, in manner hereinafter described.

Fifthly. I effect impulsion or propulsion on and along railways, common ways, and canals and over, along, or through fields by inducing or generating a well-known source of motive power, force, or influence, being electrical, whether electro-magnetic, voltaic, frictional, or otherwise. These or any of them I supply from stationary wells or batteries, whence I transfer or transmit the motive influence along a line of railway, common-way, canal, or field to put in motion apparatus and impelling machinery consequent upon the combination of method and apparatus hereinafter mentioned, and effect the other things hereinafter described. In the following parts of this specification and the drawings and plans accompanying the same numbered from No. 1 to No. 10 and the parts thereof the same figures of reference apply to all the diagrams, plans, elevations, sections, and views respectively for each distinct subject, by reference to all or any of which the varied applications, combinations, effects, circumstances, and other things referred to in the title of my patent will more plainly appear.

And, first, as to the varied application of one of the combinations of gaso-pneumatic power to engines, apparatus, and machinery, whereby and by means whereof I construct what I denominate a differential railway, drawing No. 1 as seen in plan, figure 1, elevation, figure 2, and end view, figure 3; 1, 2, 3, 4 represent the rails on a double line of railway. At a central point between the double lines I construct a fixed engine or apparatus suited to any of the motive powers herein referred to. If for gaso-pneumatic, then I combine with the said apparatus the gaso-explosive engine described in my said former specification, which is therein described in detail as well as in the method of working it, referring to which renders it unnecessary that I should do more than shew without minute detail the parts in this specification or the accompanying drawings herein. On a suitable foundation at A, figure 1, under the surface level of the railway, I frame a base, *a a a a*, of any suitable material, on which I suspend or support a cast-iron wheel or wheels, *b b b b*, in a horizontal position, figures 1, 2, 3, of such diameter as that the 4154 peripheries shall revolve at about the centre of each track of railway. On the peripheries of these wheels are grooves or flanges one inch in depth, the width of the grooves about five inches. Two of these wheels are laid parallel one to the other, and are connected with a double crank, *c c c c*, the crank journals to be at right angles to each other. The under part of the crank axle revolves in a step, *e e e e*. Over the wheels *a a a a* is a cast-iron frame, *f f f f*, bolted to the frame which supports the wheel, *bolted to the frame which supports the wheel*, for the purpose of supporting the upper end of the crank axle on the frame that supports the wheels *b* and in a central position between the double lines of rails, and in a horizontal position are placed the piston cylinders *g g g g*, whether for gaso-pneumatic or steam power, from the piston rods of which are attached the connected rods *h h h h*, uniting the piston rods with the journals of the crank axle *c*. One of these wheels, namely, the lower one, may be thrown into and out of action by the application of a clutch, as used in the common manner, and therefore allows the crank axle to revolve loosely in it. To a cross-horizontal frame I support four horizontal friction or adhesion rollers, *i i i i*, two of which revolve in the groove of each of the wheels *b*. At a point, B, and at the distance of about two miles on and along the line of way, I construct and fix in similar position and in a like manner another one of the same engines and apparatus, and at a point, C, are two similar wheels being about one mile intermediate distance between the engines A and B so fixed. I construct in like manner another apparatus of the same construction, omitting only the piston cylinders *g g* and the connecting rods *h h* and the crank axle, and substitute in lieu thereof a straight axle. The wheels at C, however, must be supported on a movable frame, K, figures 1 and 2, having rollers that move on rails or bars fixed to the foundation on which the wheels and frame move. The distance between the centres of the two wheels may be about twenty feet, and the rails or bars on which the frames move of such a length as to allow the frames and rollers to move backward and forward for a distance of about ten feet each. Between the centres of the wheels B is constructed a well, E, several feet in diameter and about twelve feet in depth. On

and across the top of the well E is laid a circular frame-work, K, for the purpose of attaching two guide-pull*ies* about two feet in
4155 diameter. The frame K has a hole in the centre through
which a chain, *x x*, passing over the guide-pull*ies*, may move. A chain, *x x x*, connected with either frame of the wheels passes over the pull*ies* and is reeved through a metal block and pulley, *m*, and from the block *m* are suspended, in the well, weights *n n n n*. This arrangement will constitute one section of about two miles in length of a double line of railway. At similar points and equal distances along a line of railway I form, construct, and fix similar engines, constituting similar stations and sections of railway. The adjacent apparatus continuing from B will be a similar apparatus to that placed at C, and at the next fixed point or station beyond the apparatus C is placed a similar engine and apparatus to that fixed at A or B, and so on alternately along the whole line of railway. All along the central line, between the double line of railway, I lay a common gas main, 2, say five or six inches in diameter, having common syphon wells and intersecting valves, all of which are permanently laid under the surface level of the railway. At each of the engines, A or B, is a branch from said main communicating with the gaso-pneumatic engine *g g*, connected with the gas mains. At stations of about ten miles apart are gas stations for manufacturing the gas to supply the mains. Along the whole line of railway, near the centre of each double line of railway, I construct trenches L L, figure 3, nine inches wide by twenty inches deep, of brick, timber, or any other suitable material, the upper line of the trench being in a line with the surface level of the railway. Along the whole length of the railway and in the centre line of the trenches L L I place a series of pull*ies*, *q r s*, at any convenient distances apart, say forty feet, more or less. These are constructed in the following manner: — a frame or standard, *p p p p p*, figure 4, plan, elevation, and section on an enlarged scale, I suspend a roller, *q*, by its axis so as to allow it to revolve freely. The diameter of this roller may be about fifteen inches and its width four inches and a half, having a groove in its periphery four inches wide and half an inch deep. In the same standard and above the roller *q* I suspend a compound pulley *r*; 1 S, by its axis
4156 S, being of a larger diameter than *r*, three feet nine inches,
whilst *r* is the same diameter as *q*, about three and a half inches wide, the axis of *r s* is allowed to rise and fall in a slot having a bearing, *t*, on the side of *q*. Under the bearing is a spiral spring, *u*, of sufficient strength to lift *r s* from contact with *u*, say half an inch above it; *r* may fall into the groove of *q* and roll freely on it. I now form a band of metal, say steel, *w w w w w w*, of a continuous length, four inches wide and about quarter of an inch thick. I pass this band round in the groove on the periphery of the wheels *b* at the station A between the friction rollers *i i* and between the nearest rollers *q r*, on the standard *p q*, and *r* of the nearest rollers may be slightly conical, so as to twist the band from a vertical to a horizontal position; and I lead the said metal band between all the pull*ies* *q* and *r*, along one track of the double rail-

way, to one of the wheels *c* at the intermediate station and around in the groove in its periphery, and so pass it in like manner between all the pull*ies* *q* and *r* on the other track of the double line of railway, the nearest pulley to the wheel *b* at *c* being slightly conical, so as to twist the band from a vertical position on the wheel to a horizontal position. I thence continue the band between the pull*ies* *q* and *r* along this track of the railway and so bring it up to the wheel *b* at A, where I unite it to the other end of the band, so as to form an endless band. A round or circular metal rope, bar, or bars may be used instead of the aforesaid band; in that case there must be grooves in the peripheries of the rollers *q* and *r* to correspond with the form of the rope or continuous bars. When curves occur on a line of way the metal band may be made to conform to it by making the pull*ies* *q* and *r* conical, so as to twist the band whilst passing the curves; and, further, if in lieu of said gaso-pneumatic cylinders at the points A B steam engines be substituted, then the line of railway may be worked by stationary steam power, and in that case the aforesaid mains may be dispensed with. On the differential railway the carriages receive their impulsion
from the impelling wheels S fixed at the points aforesaid
4157 along the line of way. In order to bring the carriages in
contact with the wheel, I suspend under the floor of each carriage a movable flange bar, 1 (figure 2, drawing No. 1, A 2), having a length equal to the length of the carriages and buffers—say about twenty-eight feet. The mov*e*able bar may be made of rolled iron, about one inch thick in the web, of the form shown in section, figure 4, the flanges 2 2 of the bar about one inch deep, and the plain surface of the bar about eight inches between. The bar is suspended below the travelling wheels in the following manner: As one method which, however, may be varied by any simple mechanical arrangement, namely, two or more parallel *p*r similar bell-crank levers, 4, to be attached to the upper flange of the mov*e*able bar by the extremity of the short end of the lever 3; the other or long end of the lever or bell crank to have attached to its upper or extreme end a curved rack, 5, into which a pinion, 6, is moved by a crank handle, 7, the action of which tends to raise or lower the flanged bar 1, so as to bring it in contact with the impelling pulley S or raise it therefrom at will. The degree of pressure of the bar 1 on the wheel S may be regulated by an index, so as to induce any required degree of adhesion between S and 1. In order to fix the bar 1 when in contact with S, I attach to the frame a long wrought-iron rod, 8, joined at the ends of each carriage by a long clutch coupling, 9, with sufficient play room. Longitudinally upon this rod I fix a strong screw-thread which works in the periphery of a pinion wheel, 10, upon the axis of which I fix two excentrics, 11, placed in such manner as to press down the bar 1 on each side of the rib by the action of the screw-rod acting upon the screw-pinion in motion by a ratchet-wheel handle, 12, near the seat of the conductor or conductors of the train. On the front end of the bar 1 I attach a bent spring steel bar, 13, of the form shown, which is in-

tended to throw each pulley *s* into motion before it comes in contact with the curved end of the bar 1.

And I further vary one of the said applications or combinations of gaso-pneumatic power with engines, apparatus, and machinery described in my said former specification, as therein shown,
4158 to apply to impel or propel vessels on canals by a further
combination of method and apparatus to effect a like purpose; to which end I construct on and along the whole length of a canal, on one or both margins thereof, a suspension rail, A A A, figures 1, 2, and 3, drawing No. 2, as shown in plan, elevation, and sectional end view, by fixing piles or pillars *a a a a* along the said margin, about eight inches square, and these constitute the sleepers for supporting a single line of railway bars. These are let into the ground to the depth of about three feet and project to a height of about eighteen inches above the surface level of the towing path and are placed about nine feet apart. On the tops of the piles or sleepers are placed common railway chairs *b b b b*, fastened down to the sleepers in any convenient manner. Into these chairs are placed the ends of the railway bars and fastened by a bolt or pin, *c c c c*. The bars are about nine feet in length and have a convex up-er surface. Along the said canal, in a line with a line of the rail, I lay down the said gas main, *x x x*, described in my former specification, of the diameter of about four inches. This main is laid under the surface level of the towing path, and to the main is attached, at suitable distances, common syphon wells for the purpose for which such wells are usually applied to gas mains. At distances of from one to two miles apart along said mains I connect bends or branches *d d d d*, and to these, where they occur, I apply and connect gas-valve mains B B B. On each of the bends *d* I apply an intersecting valve for cutting off the communication between the gas main and the valve main, for which purpose I apply a lever action, the lever *e e e e* being made self-acting and is connected with another lever, *e*, by a wire, *f*, shown in a waived line. The valve of the valve main is constructed in the same manner as the gaso-pneumatic-valve main described in my said former specification and may be of any required length, say from one hundred to one hundred and fifty feet in length. On the rail *a* I suspend an impelling machine, C, as in plan, elevation, and sectional end view. This I construct in the following manner: To a cast-
4159 iron crutch or frame, *g g g*, I attach travelling wheels *h h h h*
by their axes in a slot in the crutch of the diameter of about fifteen inches. From the crutch are suspended weights *k k k k*. These are firmly attached so as to be inflexible. They are placed near the ends and on each side of the crutch. These are intended to support the travelling wheels *h* in a vertical position by suspending the principal metal of the weight below its centre of gravity. In the middle part of the crutch or frame between the travelling wheels *h* are suspended by axes two friction or adhesion wheels *l l l l* of about two feet diameter and one and a half wide on their peripheries, which are squared. These are pressed against the sides of the railway bars *a a a* by a strong spiral or other springs pleced

on one side of bearing blocks — as to regulate the required degree of adhesion or pressure against the railway bars. On the same ax*is* which carry the friction wheels *l* are attached pull*ies* *m m m m*. These pullies — about two feet in diameter and about two and a half inches wide and have circular grooves in the peripheries for the purpose of carrying a cord or tow rope, and the pull*ies* may be so arranged as that the peripheries may roll on the other and so press the cord when in the groove. The pressure of the friction wheels will tend as well as the weights to maintain the travelling wheels in a vertical position. To and on one side of the frame or crutch I attach, in a vertical position, by bolts, a tongue or compressed pipe, D D D, of the form shown in plan, horizontal section, elevation, and end view, being the hollow tongue described in my said former specification. On the upper surface of the tongue I connect a union joint or screw of the diameter of three inches. The machine so constructed I denominate the dynamic impelled. In a canal boat or vessel, E E, I fix the gaso-pneumatic explosive engine G G described in my said former specification or any modification thereof, to the piston of which I attach a connecting rod, *m*, to the journals of a crank or cranks. In the vessel E I place a horizontal fly-wheel, F F, of any convenient diameter, supported in any suitable manner, on the top of the crank axle. The fly-
4160 wheel may be placed under the deck of the vessel or under
the floor. On the upper surface of the fly-wheel I attach a pulley, *o o o o*, by pins to its rim or arms; the connecting rod *m* may be united with the crank journal or journals. In any convenient situation in the vessel, either under the deck or over the deck, I place a reservoir, 2 2, for gas; this may be in the form of long wrought-iron pipe or pipes of light construction and of any convenient length and about twelve inches diameter. In this reservoir I place a flexible diaphragm, being the diaphragms of the gas reservoir described in my said former specification. This reservoir communicates by a pipe with the explosive engine G, and from another pipe, 3, connected with the reservoir, of the diameter of, say, 3 inches, I connect by a union joint, flexible tube, or pipe, P, by one of its ends; this tube may be about three inches diameter, of any convenient length say about the length of the tow-line or cord of the vessel; the other end of the flexible pipe I attach by the union screw on the tongue D, and so unite the reservoir in the vessel with the said tongue. In the tongue D is an intersecting valve, namely, the intersecting valve described and shown in the gaso-pneumatic engine referred to in my said former specification. I apply one of the said sources of motive power, namely, the said gaso-pneumatic power, by a farther varied combination of method and apparatus, to another useful purpose, namely, the purpose or purposes of a fire-engine; for that object I vary the mechanical arrangements, or some of them, of the gaso-pneumatic locomotive engine described and shown in my said former specification, to which I refer, referring herein also to the accompanying drawing No. 3, figures 1, 2, 3, in plan, elevation, and end view. In these figures *a a a a* are the travelling wheels, *b b* the frame, *c c* the springs, *d d* the axles, *d* 1 *d* 1

the crank axle, *d* 2 the fly-wheel, *e e* a gas chamber, *g g* the piston cylinders, *h h* the slide-boxes, *k* a double-acting air or gas pump, *k k* 1 another double-acting air pump, *l l* a supply pipe leading from the gas chamber *e e* to the globular explosion chamber M M 1, on which — igniting slides *i i* and safety valves *j j*; *n n* 4161 branch pipes leading from the explosion chamber M and M 1 and into the slide-boxes *h h*; *o o* is a four-way valve or cock intersecting the supply pipe *l* and communicating with the explosion chambers M M 1; *p* is a leaver fixed on the top of the four-way valve and is attached to the rod *q*, which is connected with the lever *r r*, and so to the excentric S S on the crank axle *d* 1; *t t* are the guides and *u* the frames, *v v* the connecting rods, *w w* the reversing gear attached to the reversing bent lever *x* 2 *x* 2; *y y* is a bent lever, one part of which is connected with the piston rods of the gas and air pump *z z*; the middle part has a rack, on which is an adjusting chuck, *z* 1 *z* 1, at the end of an eccentric rod, *z*, on the crank axle *d* 1. In the fire-engine there are stuffing boxes at both ends of the cylinders *g g*, through which the rods 1 and 2 of both pistons work. — one end of the frame of the fire-engine are fixed two single-acting force pumps 3 and 4, connected with the water tank 5 5 5 by square water-ways 6 6, in which are placed common lifting valves. To each of one end of the piston rods 1 and 2 are solid plungers 7 7, working through a stuff space, 8 8. 9 9 is a metal globe communicating with the water-ways of the force pumps 3 and 4, on which one or more branch pipes 10 10 may be attached by union screws. 11 is a metal air globe, on the top of which is a pressure valve, 12 12. At the forward end of the fire-engine there is only one wheel, being an ordinary swivel wheel acting under an arched end frame. 13 13 are long screws, on the top of which are hand wheels for screwing the rods down against the ground, so as to steady the engine while in action. To the turn-plate of the front wheel of the engine may be attached a common tongue or shaft, to which horses may be geared for the purpose of drawing the engine from place to place. On a portable drum wheel, which may be placed on or lifted from the engine, may be wound two or three hundred feet of a cylindical flexible pipe about from an inch to an inch and a half internal diameter; this may be made into lengths of fifteen or twenty feet and united at their ends by union screws of the size and thread ordinarily applied to common gas-4162 service pipes or gas fittings. Several corresponding union screws, 14 14, may be attached to the gas chamber *e e* of the engine, by which one or more flexible pipes may be attached to it.

I further vary my methods of impelling vessels on canals by applying another kind of motive power, namely, the motive power of steam in combination with parts of the apparatus and machinery already described in its application to gaso-pneumatic power; to this end I construct the before-mentioned rail A A A, but I dispense with the use of the gas main and all their attachments and connexions, and I dispense with the tongue D, with its connexions (and I dispense with the flexible pipe P), with the exception of the construction of the dynamic impeller A. Figure 1, drawing 4, remains as before described, only that I further add to it by constructing a circular rail, *a a a*, which I divide into three parts, as shown by the moveable stop-joints *b b*. The top of the curved rail is the same diameter as said rail A and has the same convex surface.

Figure 2 is a canal-boat designed for goods or passengers; in this boat may be placed a steam engine of high or low pressure; *c* is a horizontal fly-wheel, supported, as before, on the top — a crank axle, to the journal or journals of which the connecting rod or rods of the steam engine may be united. On the upper side of the fly-wheel a pulley, D, may be fixed, as before described. An endless cord or tow-line, *e e*, may be passed round the groove of the pulley of the fly-wheel, and also round one of the pull*ies* on the off side of the dynamic impeller. A friction roller, *f*, may be fixed to roll on the periphery of the pully *d*, and press the tow-line by revolving in the pulley. The object of the curved rail is to enable one dynamic impeller to pass over the back of another impeller, for which purpose the rail is jointed as aforesaid.

In that part of my said former specification whereon two sources of motive power therein described *as* applicable to field operations in agriculture I refer to drawing No. 1 accompanying said former specification, and also drawing No. 5 accompanying this specification, wherein D is the locomotive impelling engine in said
4163 drawings 1 and 5, to both of which the said letters of reference in said former specification apply. In No. 5 the stuffing box placed on the vertical column *x* 1, in which the end hollow axis *x* of the drum *w* revolves, is a fixture. The flexible pipe S, drawings No. 5, should be three inches internal diameter and of any convenient length, say two hundred and twenty yards.

I apply one of the methods of motive power or influence to the other things referred to in the title of the present specification, reference being had to the drawings hereinafter referred to, namely, to the things hereinafter described, all of which result from the combinations of methods and apparatus hereinafter described; and 1st, in one of the methods of constructing the roads or ways on which carriages may be impelled and by which apparatus may be put in motion or action the combination of methods, engines, and apparatus hereinafter described are the bases upon or from which all the actions, effects, or things result or obtain. The power or influence which I apply is the electric influence in any of the forms which I may find most convenient, by any of the well-known methods of inducing the electric currents, whether voltaic, electro-magnetic, frictional, or otherwise, and whose induction, tension, or influence may be transferred, transmitted, or induced at points or places distant from prime sources or batteries. One of the objects to which I apply said motive force or influence is to put engines, apparatus, machinery, and implements in motion in, along, over, or through fields for agricultural purposes; with that view I*n* erect in any given area of land, say one or more square miles of land, a station, A, drawing 5, placed in a central or any convenient situation. A is a building, in which I construct and place an electric battery or batteries of any of the common or well-known constructions, or I construct wells or tanks A A 1 in any part or parts of such ar*rear* of any suitable material or any required size or form; those I place under the surface level, the tops of which are so far below the surface as that they may be covered up with soil, so as not to interfere or impede agricultural operations.

4164 From the station A or any of the stations A A 1 I lay down a system of mains or pipes, B B B B, of the diameter of about two or three inches, united by flanged joints connected in the common manner. These may be laid through various fields, either below or above the drainage, and in any direction, as shown by the dotted lines passing through B, one of said mains B. One is uncovered to show its position under the surface level. All along said mains, at convenient intervals of from one — two hundred yards, I erect short vertical branches, *a a a a*, communicating with the pipes B. These terminate in a box, *c c c c c*, having a moveable lid, the top of the box to be so far below the surface level as not to interfere with tillage. From the station A or from the wells A 1 I lead through the pipes B continuous metallic wires, rolls, or ribands or bundles of fine wires, as shown at 1 2 3 4 5 6, drawing No. 6, say of copper, of any required thicknesses or surfaces. The wires, rods, ribands, or bundles may be insulated by silk and varnished in the common manner, so that one wire or rod or riband or bundle shall not be in contact with another. These may be laid in pairs and colored with different colors—for example, black and red, blue and yellow, brown and green—the black and red corresponding with the positive and negative poles of the battery, and in like manner the blue and yellow and the brown and green and so on for any other pairs and colors. Any pair so arranged may be turned into the vertical branch or branches *a* and terminate in the box or boxes *c*, in which they may diverge and be fixed at points *d d*. The apex of *d* may be sufficiently long to bend over to *d* 1, with which it may be brought in contact by a screw and from which it may be released at will. A similar arrangement is made in all the boxes *c*. All the said wires, rods, ribands, or bundles must be so properly arranged and be so continuous as that when connected in the boxes or the pairs united with any other wires connected with apparatus or machinery and their ends at the stations or wells are brought into proper contact with the positive and negative poles of a battery they shall form or constitute proper metallic circuits.

4165 The wires, rods, ribands, or bundles may be of any desirable dimensions suited to convey by their means the largest intensity, effect, or influence *or* what is called an electric current when the wires and battery are properly — for conveying or communicating the electric force and when the electric influence is continued under induction or tension and so long as the ends of the wires forming the metallic circuit are in proper connection with the poles of the battery or batteries at the stations A or A 1.

In order to put imp*el*ments into action for field or other operations, namely, such imp*el*ments and apparatus as are referred to and described in my said former specification, I construct a locomotive engine, D, drawing No. 5 A, with similar wheels *a*, frame *b*,

spring *c*, axle *d*, or crank axle *d* 1, having the columns *x* 1, revolving drum W, the wheels *a* having the studs 1 2 3 4 or any other implements described as appertaining to said locomotive engine in my said former specification, but dispensing therefrom with the cylinders *g g* and their appurtenances and the piston rods *h* and the connecting rods *k* and the guide frames *o*. The drum W may be of smaller dimensions than therein described, namely, ot the dimensions of three or four feet diameter and of the width of two feet, but suspended in the manner formerly described. Around the said drum I wind a coil or pair, S S S S, of the aforesaid wires or bundles, of any required length and dimensions—say from one to three hundred yards. One extremity of said pairs I pass through the drum hollow axis and through the fixed stuffing box; the other extremity I attach and properly adjust to a similar pair, terminating in the box *c*, for which purpose the ground may be opened and the lid of the box raised. To the locomotive engine D I apply an electro-magnetic engine, namely, any well-known and effective electro-magnetic engine or machine capable of imparting motion to machinery—for example, Taylor's (patented) electro-magnetic engine or one on the principle applied as hereinafter described. If Taylor's engine be used, then I apply one or more of said engines to the axle *d* on the locomotive engine D, to the poles of the magnets, which I connect, and properly ad-
4166 just the wires S S, so that from said pole of the electro-mag-
netic engine, on the axle *d*, through the pair of wires S S, passing through the stuffing box on the column X 1, on through the hollow axis, through the continuous coil on the drum, to the corresponding wires connected as aforesaid in the box *c* on the vertical branch *a*, thence through the main B 1 and the main B to the station A and properly to the poles of the battery therein, or when connected in like manner at the wells A 1 or any of them, so that when the aforesaid connections are ma*id* and properly adjusted there shall be an unbroken communication between the battery at the station A or wells A 1 or any of them and the locomotive engine D, so that between station A or A 1 and D there shall be a proper metallic circuit established.

And, further, I apply the said method or source of motive power, to wit, the electric, to another of the things referrred to in the title of this specification, namely, to the preservation of life and property on railways by acting on br*eak*s to stop and prevent the collision of trains. With that view I lay down all along a line of railway, in a central position, between the tracks of a double line, a light railway bar or bars, P, figures 1, 2, cross-section and elevation, drawing No. 7, supported on cross-sleepers when such are used or on one line of block sleepers when such are used; the railway bar may be fixed in chairs about nine feet apart or bolted on the cross-sleepers or into the blocks when such are used. The form of the rail may be of the same as shown in cross-section H, wherein *a a* is the cross-section of the railway bar, having flanges *b b* on the upper surface, into which is let continuous bars of hard wood *c* about two inches square; the bar is a hollow bar, as at *d*. I

divide the line of bars H into half-mile lengths or sections, No. 1, No. 2, No. 3, No. 4, by continuing a space of about three feet between the bars in the middle of the section, and I so continue them in half-mile lengths by similar spaces all along the line of the railway except where points or switches occur; at those places the spaces may be as many feet as to prevent their action or interfere
with trains when passing on them. All along the line of
4167 railway, say of one or two miles or more or less distance
apart, at convenient points or places I construct the aforesaid battery or batteries. From these batteries I lead a pair of metallic rods or wires of any required dimension or dimensions, having continuity as before described and insulated as before described; these I lead through the space or cavity *d* of the bar H on the angular surface of the wooden bars *e*, as at *e e*, continuous copper rods or wires *x x* 1 of any required dimensions, say three-quarters of an inch wide on their upper surface. These are attached to the wooden bars *e* by copper pins. The rods or wires are each as long as the said section of the bars. At the extremity of the half-mile section *a* 1 *a* 2, in plan form *a a*, the rod *x* communicates by contact with the rod or wire *x* 2 in the cavity of the bar, and the rod *x* 1 communicates by contact at the same extremity with the wire *x* 3 in the cavity *d*. From that end of the bar *a a* the wires *x* 2 and *x* 3 lead to one of the aforesaid batteries, No. 1, plan view, drawing No. 9 (where the ends of the pair of insulated wires communicate with and are properly adjusted to the positive and negative poles of said battery), and from another division of said battery or an independent battery at the said point or station another similar pair of insulated wires lead to the next succeeding half-mile section of the railway bar H, No. 2 in plan, drawing 9, where the said pair are in a like manner connected or adjusted, or in section No. 1, and a similar pair of insulated wires lead from the same station or battery A to similar sections No. 3 and No. 4 on one line of the railway, and from the same section of battery or batteries similar pairs of similar insulated wires lead in like manner to similar sections on the parallel line of railway. The rods of wires *x* and *x* 2 and *x* 1 and *x* 3 from a perfect continuity from the beginning of the section *a a* along the wires *x* and *x* 1 to the extremity of the section *a* 1 and *a* 2, when they join the extremities of *x* 2 *x* 3, and thence lead through the cavity *d* to the station of battery or batteries A, where, being properly adjusted to the poles of
a battery, — established a metallic circuit whensoever the
4168 wires *x* and x^1 may be made to communicate by contact,
and so in like manner do all the wires of all the sections when properly adjusted to poles of battery or batteries. In order now to transfer or communicate the electric influence to breaks connection with locomotive or other vehicles on railways I suspend from a moveable joint fixed on a wooden frame attached to a locomotive engine in elevation D, drawing No. 7, and as seen also in elevation No. 8, a pair of copper conductors, *g g*, figure 1, No. 8, and in figure (7) and in No. 7. This is suspended by a moveable joint attached to said wooden frame fixed on the locomotive engine. To

the lower extremities of the rod *g g* I attach by another moveable joint what I term an electro-magnetic coupler, *h h*, composed of two masses of copper of the form shown in section *h h*, elevation drawing No. (7) and in elevation No. 8. These are attached to a wooden block, *k*, by wooden pins *i i*, the lower extremity of *g g* being connected with the upper surface of *k*. The couplers *h h* are in contact with wires $x\ x^1$ in elevation drawing No. 8 and in drawing No. 7, x^1. From the upper extremities of the conductors *g g* a pair of insulated wires, *m m*, in elevation (drawing 8) pass through wooden guides *n n* attached to the locomotive. In a wooden frame fixed on the locomotive I place an electro-magnetic engine—for example, say, Taylor's rotatory engine. To the wire of one of the poles of the magnet or magnets I connect a corresponding wire, *m*, and to the end of the wire of another pole of the magnet I connect the other corresponding wire, *m*, by which means I complete a metallic circuit by means of the electro-magnetic coupling slide *h h*, because whilst one of the rods or wires leading from one of the poles of the battery through the wire x^3 from the end of the section *a a*, through the cavity *a*, to the wire x^1 at the extremity a^2 and by contact with one of the couplers *h*, thence through one of the conductors *g* and one of the wires *m* through the guide *n* to one pole of the corresponding wire wound round a magnet of the rotatory engine; then from the other pole of the magnet I connect the other corresponding wire *m*, which leads to the other conductor *g*, to the other 4169 coupler *h*, to the rod or wire x^2 in the cavity *d*, and so long to the other pole of the battery at A, to the pole of which said pair of wires are properly adjusted. so that when all the said connections are properly arranged a metallic circuit will be established, in which an electric current may be induced and through which it may be transferred. On the axis of said electro-magnetic rotatory — I attach a pulley, 1, about twelve inches diameter, insulated at its axis by ivory bearings, to the periphery of which I attach one end of a wire or cord, 2, and pass around the pulley 1, over which it passes to a lever, 3, on the whistle of the engine, with a branch cord or wire, 1, to the lever 4 of the steam-throttle valve of the engine.

And, further, instead of attaching the apparatus herein last described to the locomotive engine I place the same or a similar apparatus with a similar arrangement to one of the carriages of a train for the purpose of acting upon the br*eak*s of a carriage to impede or stop their progress, and from such carriage and the apparatus, when placed thereon, lead a cord of wire to the whistle and steam-valve of the engine in similar manner as before described, or, instead of Taylor's rotatory engine, I construct an electro-magnetic engine, P, of any required dimensions, figures 1, 2, 3, elevation drawing No. 10, in the following manner—that is to say, supported on a cast-iron frame, *a a a a*, laid on a suitable foundation, or constructed on columns *b b b b*, I erect a column, *d d*, on the apex of which I suspend a vibratory beam, *e e e e*, on a platform, *g g g g*. I construct and fix one or more electro-magnets *h h h h* of any required dimensions or capacity by any of the common and well-

known methods, each having a magnetic surface, say 1 2 3 4, sixteen square feet, more or less, according to any required force or power of an engine. The upper surfaces of these may be laid in a horizontal, angular, or vertical position on moveable points or axis *i i i i*. I connect one edge of flexible metallic plates *k k k k*, having superficial surfaces equal to the area of the magnets. When the plates *k* are connected with the axis *i* the flexible plates may lay flat on
the magnets *h h h h*, on those sides of the plate *k* which
4170 *which* are on the sides opposite the surfaces. In contact with
the magnets are raised surfaces or beads *m m m m*, riveted on the plates or rolled in the solid mass. These lay across the plates in lines which are at right angles with the beam of the engine, and must be of such proportions and so far one from the other as not to neutralize the required degree of flexibility in the plates in their actions hereinafter described. On the centre parts of the raised surfaces are eyes *n n n n*—iron joints intended to form movable joints. From the ends of the beam 1 2 are suspended movable connecting links, 2 2, which are keyed onto the axis 3 3, into which are keyed flexible steel bar connecting rods *p p p p*, or the rods hereinafter described, which terminate in the moveable joints *m m m m*, to which they are held by bolts or pins. The connecting rods so formed are of such lengths as that when the beam of the engine is in a horizontal position the connecting rods *p p p p* shall stand in diverging lines from the points *m m m m* to the links into which they are keyed, 2 2. From points 4 4 on the beam B B, in manner hereinafter shown, and from a point, 5 5, on the beam, I suspend a connecting rod, *q q*, which is connected with the crank *z*, on which is a pinion wheel, S S, which gears into a spur-wheel, — may be attached to the fly-wheel *u u*, moving on the centre *v*.

And, further, having in the foregoing part of this my specification described and shown the combinations of method and apparatus whereby and by means whereof I am enabled to apply and use one of said forces or influences, to wit, electricity in any of its forms, and shown how the same may be laid down on a line of railway for the purpose of acting on the br*eak*s of carriages and putting and impelling machinery in motion, I further vary said application by placing an electro-magnetic machine as the moving power on a locomotive engine for the purpose of impelling trains of carriages; for example, if Taylor's rotatory wheel, then on the axle or axles of the locomotive; or if one on the application of the electro-magnetic principle before described and shown in drawing No. 10,
which may be varied in its forms and construction so as
4171 suitably to apply to locomotive-impelling engines, then I
put such machines in motion or continue them in motion along a line of railway by taking up the electric force from the wires *x* and x^1, arranged as aforesaid, and the electro-magnetic slide *h h*, which communicates to the impelling machinery in manner aforesaid and establishe*d* a metallic circuit or circuits in manner before described; and, further, when I apply the said source of motive power or source to impelling vessels o*r* canals I apply the said arrangement of the metallic circuits to the rail *a a a* along a line of canal, slightly

varying the mechanical arrangements by supporting the wooden bar or bars *c* on each side of the rail in any convenient manner and bringing the electro-magnetic coupling slide down on each side of the rail to the wires x and x^1, which should be attached to the bars *c c*, all the required parts being properly insulated; then on the aforesaid dynamic impeller I place an electro-magnetic engine, being either of those referred to, either the aforesaid Taylor's or that on the principle applied and described and shown in drawing No. 10. These, by any simple gearing, may put the travelling wheels in motion, or either of the said engines, being placed in the vessel *e*, may put said fly-wheel, pulley, and cord in motion; but in lieu of said flexible tube, already described, conducting wires, communicating with the engines through the said electro-magnetic coupling slide, may be applied, and by their action impel vessels on canals; and in like manner said electro-magnetic engines may be applied to impelling machinery on the railway, the combinations of which I denominate the differential railway, by substituting for the gaso-pneumatic engines *g g* electro-magnetic engines, which may be used to put said impelling wheels which give motion to the metallic bands, ropes, or bars before described into motion; and, further, having shown some of the methods by means whereof I apply one of the said sources of motive power, to wit, electricity, and, amongst other things, described impelling engines in motion from fixed points or stations, I further vary my methods, as well along common roads or ways, along, over, or through common roads or ways and streets or places, and to manufacturers' houses 4172 or buildings in a like or similar manner as I have already described them along railways and through fields, and when so applied for the purpose as in manner herein described for putting said impelling engines or any similar impelling engines into motion for manufacturing purposes. In making such application of said motive force or influence I form on, along, over, or through from stations as aforesaid, properly established, electric metallic circuits, and to and with the said engines or any similar constructed engines placed along or in said ways, streets, places, buildings, or manufactories, I unite said engines with said metallic circuit and the said battery or batteries at stations as aforesaid, which said battery or batteries may be placed in any convenient situations as stations and constitute a part of said metallic circuit or circuits and when so established put engine, apparatus, and machinery in motion in manner aforesaid. Having now described the several combinations of methods and apparatus by means whereof I apply said several motive powers or forces to the said several uses herein described, I hereinafter set forth and described the operations of all the applications successively, reference being had to the drawings and figures applying to each subject herein and in the said former specification described.

Firstly. Differential railway. Operation: Gas being supplied for said gas stations, and fitting said mains along the whole line of railway, in which mains the gas may be under compression to any required degree, but say under a pressure equal to a barometric

pressure equal to several inches of mercury, the intersecting valves of the main at the engines A and B and at similar stations along the line being opened, gas will flow into the reservoirs of the engines and into the gas pump *k* and through the supply pipe *l*, through the four-way valve *o o o o*, into one of the explosive cylinders M or M 1, when it will mix with atmospheric air and f*ro*m an explosive mixture that may be ignited through the holes under the slides *i i* of the globes, and will dilate and pass through
the branch ways *h h*, on the opposite heads of the two
4173 pistons in the cylinders *g g*, drawing No. 1. The 2 pistons
will be forced in opposite directions through the cylinders.
The piston rods will give motion through the connecting rods *h h h* to the crank axles *c c c* of the wheels *b*, which will revolve to the metallic bands *w w*, by their adhesion on the periphery of the wheel *b*, with which the bands are kept in close contact by the adhesion rollers *i i i*, the alternating actions of said piston and connecting rods being continued by the working of said engine, as described in said former specification. The metallic bands, bars, or ropes will be drawn along the double tracks of railway between the pull*ies* *q* and *r* all along the line, which will put them in motion on both tracks of railway, the lower one, *q*, in the line of direction of the metallic band, and the upper one in a direction opposite to the line of direction or motion of the band. When the compound pull-y *r* and *s* are pressed down by any weight, so as to bring *r* in contact with the band, and when no weight presses upon the driving pull-y *s* of the compound pull-y, then the before-described springs lift all the compound pull*ies* so high above the band as not to be in contact with its upper surface, and in that case no motion will be given to any of the compound pull*ies* along a line of railway; but when the pull*ies* *r* of the compound pull*ies* are pressed down in contact, and motion is so given to them by the pressing band *w*, then, the pull*ies* *s* being of twice the diameter of the pull*ies* *r*, the pull-y *s* will revolve so that its periphery will move through twice the space of the pull*ies* *r*. Thus if the metallic band *w* be moved in one direction with a motion or speed of, say, eight miles an hour, then the driving pull*ies* *s* in contact with the band will move through spaces with a velocity equal to twenty-four miles an hour. The revolution of the wheels B at the stations A and at all the similar stations will put the wheels *b b* in operation at the station C or similar stations all along the line of railway. The band which moves through the said trenches L is kept properly stretched at the points C or any similar points by the weights *n n n*, suspended in the wells E, which act on the mov*e*able
frames at K at the points C, through the medium
4174 of the chains *x x*, connecting the frame and passing over the
guide pull*ies* on the top of the wells, and which are reeved
through the metal blocks and pull*ies* *m*. By means of clutches or any simple gearing either of the sections of the bands mov*e*ing between the stations A and station C or that section lying from station A in the opposite direction may be put into or out of motion by disconnecting the upper or lower wheels *b b*. If now on the

double line of differential railway trains be placed on the up or down line of the railway the carriages of a train or any required number of them having the adhesive flanged bars 1 2, drawing No. 1, A 2, with their connecting apparatus before described attached to them, the said bars 1 and 2 or some of them, in order now to start the trains and move them over the up and down lines of railway by turning the handle 7 on the pinion 6 round it will move the rack 5 on the quadrangular lever 4 and cause it to move in the direction of the arrow near it. This will cause the prop of the same lever 3 and its support 3 at the end of the bar to move in the opposite direction and in the line of the arrows near them, and cause the bar 1 to descend and press on the driving pull*ies* S. If on a pull-y fixed on the pinion 6 a cord or wire be fixed so as to reach to similar quadrangular levers 4 4 attached to the other carriages of the train, then when motion is given to the pinion 6 it will move the other levers 4, and so bring the bars attached to them to bear on any of the other driving pull*ies* S. The cords may be attached and detached on changing carriages. The bars 1 may thus be pressed down to effect any degree of adhesion on the pull*ies* S consequent upon the weight of the carriage and the yielding of the springs that support the carriage; but if to effect greater adhesion between the bars 1 and pull*ies* S on ascending inclined planes be required, then the lever of the racket wheel 12, being moved backward and forward, causes the rod 8 to turn the screw, which acts in the teeth of the screw-pinion 10 and causes it to turn, bringing down the excentric cams 11 to press the bar down with greater force, and so any of the other bars in the train be pressed down in like manner.

4175 When the band W is in motion and moving in an opposite direction to the moving train the weight of the carriages overcoming the springs that lift the pull*ies* *r s* from contact with the band causes *r* to descend on *w*, the driving pull*ies* S would be put into rapid motion, and rolling on the bar 1 impels the train of carriages forward. Some of the bars of the trains will always be on some of the pull*ies* S of the railway, and will be impelled forward by them in like manner. When the bar of the forward carriage has passed over one pull-y and approaches another pull-y S the flexible steel bar 13 will touch the next pulley, and rolling over and pressing on it will put it in motion before the curved end of the bar 1 begins to move over it, and so on for all other pull*ies* in advance of a moving train. When a train is moving on the up line in any section of the railway another train or trains may be moved on the down line of the railway by the same band on the same section of the railway, and as the train passes the stations A or C or any similar ones, then the forward carriage, leaving the pull*ies* acted upon by one band on one section of a railway, runs on to the pull*ies* S put in action by the band moved on another section of railway, and so on along the whole line of railway. When it is desired to stop a train the action of the handle 7 raises the bar 1 from contact with pull*ies* S, and by the cords leading the other levers 4 on the carriages raises all the bars 1, and the action of br*eak*s in the common manner stops the train. When action is given to the ratchet 12 and the rod 8 it produces pressure on the other bars of the carriages of the train by means of the coupling jaws 9, which are in contact and that slide one in another. Operation: The gaso-pneumatic power to effect propulsion on canals, reference being had to drawing No. 11, figures 1, 2, 3, the gas main *x* being filled with gas from said gas station, and the gas being under moderate pressure, filling mains all along the line of the canal, and the intersecting valve *d* of the valve main B being opened, gas will flow into the valve main through the hollow cavity of the tongue D, through the flexible tube P, and through the pipe 3, connected with the reservoirs 2 2 in the boat E. In the reservoirs are the flexible diaphragms described in the said former specification. When the explosive engines G, 4176 which is the same as the explosive engine described in the said former specification, is brought into action, the gas from the reservoir 2 2 will flow, as before described. The explosion globes in which the explosive mixture is formed and igniting will dilate as aforesaid, and will expand on either side of the piston, whose rod will give motion to the connecting rod *m* and crank axle of the fly-wheel F, and consequently to the pulley *o*. This will give motion to the cord acting around the pulley *o* and pull*ie*s *m*, figure 3, and to the adhesion wheels 1 1, figure 2, which will cause the traveling wheels *h h* to roll forward on the convex rail A, and in moving will impel the boat E. When the dynamic impeller advances on one of the valve mains B and the tongue enters the flexible valve, the dynamic impeller coming in contact with the lever E, figure 3, will move another lever, E, and another lever on the intersecting valve *d*. Whilst the tongue is passing through the flexible valve the gas flows as before through the valve main B and the flexible pipe P into the reservoir, 2 2, as before, thus suppl*u*ing the reservoir with gas to keep the engine in action until the dynamic impeller arrives at another valve main along the line. When the tongue D has moved through the flexible valve, the dynamic traveller acts upon the lever *e*, on that end of the valve which it is leaving, and so to the lever *e*, at the other end of the valve, through the wire *f* to the intersecting valve, which it closes, and so on through all the valves along the line of canal. The pressure of the adhesion wheels 1 1 can be adjusted by their springs, which are pressed upon by a screw-bolt to increase the adhesion, and so the impelling power may be increased. In order to apply one of said sources of motive power to impelling engines or machinery — operation — I use the locomotive gaso-pneumatic engine described in said former specification and the drawing No. 4, therein mentioned, reference being also had to the drawing No. 3, figures 1, 2, 3, accompanying the present specification. I apply the use of the said engine in combination with method and apparatus for the purpose of fire engine, *is* required; for the purpose last afore- 4177 said, horses may be harnessed to the pole or shaft on the frame *b*, near the wheel *a c d*, to drag it to the place of conflagration, on arriving at which place the flexible pipe before described is unwound from the portable drum. One end is attached

to one of the unions, 14, on the gas reservoir *e*. The other end should be taken to the nearest service pipe connected with the gas mains laid down in any public street or other place, or to the fittings in any building, by a union screw or screws that will fit any of the given diameter in the ends of service pipes. A communication is thus formed between any such gas mains or fittings and the fire engine, the public mains being charged with gas, or the gas, being let on, will flow from such said mains or fittings to the gas reservoir *e*, on the engine, and from it through the supply pipe 1 and the four-way valve *o* into the explosive globular chambers *m m* 1, where it will mix with the atmosphere and *from* an explosive mixture. The slide *i* being then moved and a light applied to the aperture under it explosion will take place in that chamber, and consequently dilation will ensue; passing down through the ways *h h* to the opposite heads of the piston in the two cylinders *g g*, will move the pistons and rods, which give motion through the connecting rods *v v* to the crank axle *d* 1. Whilst explosion and dilation is proceeding in the chamber *m*, the gas pump *k* and air pump *k* 1, being put into action by the first stroke of the engine, forces regulated quantities of gas and air through the supply pipe 1, through the passages of the four-way valve *o*, into the chamber *m* 1; the slide *i* being open on that chamber by the action of the lever *q*, and the lever *p*, on the four-way valve, being adjusted in its passages from the chamber *m* 1 through the passages *h h*, and the ways of the cylinders *g g* being adjusted by the slides on the cylinders, which are regulated by the eccentrics *s s* and their rods, dilation will now take place through the ways *h h* to the opposite ends of the cylinders *g g*, when, the pistons and rods being thus continued in motion, which is communicated through the connecting rods *v* to the crank axle as before, a continued action in the engine will ensue. The flywheels *d* 2 *d* 2 equalize the motion of the working parts
4178 of the engine and the pumps *k* and *k* 1, the pistons of which
are acted upon by their rods *z z* on the bent lever *y y*, and so regulated quantities of explosive mixtures are formed and flow into *m* and *m* 1 in regulated quantities aforesaid, such regulation being measured by the action of the bent lever *y*, the length — whose motion is regulated by an eccentric, *z*, on the crank axle *d* 1 and an adjusting slide and thumb-screw moving in a rack on the lever *y*. On one end of the frame of the engine I fix two single-acting force pumps, 3 4, leading from the ends of which into a tank, 5 5, suspended under the frame of the engine, are water-ways 6 6. On the force pumps are stuffing boxes 8 8, through — solid plungers 7 7 work, each being connected with one of the piston rods of the cylinders *g g*. In the ways 6 6 there are common clack or lifting valves. The action of the piston *g g* putting the plungers 7 7 in motion, water being in the tank 5 5 will be drawn into the force pumps and into the globular chamber *g* at each stroke of the pistons in the cylinder *g*. The upper globe 11 is an air chamber in which the air will be compressed by the rising of the water into it, so as to induce a more continuous stream through the branch pipes attached to the

screws 10 10, through which water may be forced in large quantities. The bent lever *x* 2, acting on the reversing gear W, reverses the motion of the pistons and slide. The screws 13 13 are screwed down onto the ground to steady the action of the engine.

In order to apply one of the said sources of motive power referred to, to wit, steam power, in combination with method and apparatus, reference being had to drawing No. IV, Fig. 1, 2. Operation: In the canal-boat I place a steam engine which gives motion to the fly-wheel G and the pulley *d* and the cord *e e*, which, passing the impelling pullies, give motion to the adhesion impelling wheels and a forward motion to the dynamic impellers *a a a* which impel the boat through or along the canal. In order that a single line of suspended rail may suffice to impel vessels in opposite directions of the canal I cause one of the dynamic impellers to move over the
curved rail on its upper surface, against the sides *a a* of which
4179 the adhesion travelling wheels act to move the one impeller
over the other impeller and so again onto the rail A. The momentum with which the two impellers meet from opposite directions will assist this action. The cord *e* of one of the boats, to wit, the cord acting on the under impeller, should be slacked by shutting off the steam, stopping the action of the fly-wheel and pulley, so that the other boat may pass over the slack cord, the cord of the other boat being in motion whilst the upper impeller is passing over the under impeller. Electro-magnetic force to impelling machinery for agriculture. Operation, reference being had to drawing No. V and drawing V *a* and the letters of reference therein: I induce chemical action in the batteries placed at the stations A or A 1 and so generate electrical influence, the force of which, acting through the metallic circuit established as aforesaid between said stations and the impelling engine D through the mains *b* and the vertical branches *a* and the wires *s s* to the magnet or magnets of said rotatory engine or engines or either of them or any modification thereof, an electric current passing through the metallic circuit aforesaid will put the impelling engine in motion, will move D over or through fields, and put agricultural implements in motion such as or similar ones to those described in the said former specification. As the engine advances, the drum, being put into action by the gearing aforesaid, turns the *drum*, unwinds the insulated wires *s s*, and lays it off on the ground, and when the impelling engine reverses its action and returns towards the point of its departure or near to where the wires *s s* are attached in the box *c* of the branch *a* the drum again winds onto it these said wires so before laid off on the ground. In order to stop the action of the engine the metallic circuit is broken by the common methods and again established at will. When the impelling engine has operated for a given distance along or near to one of the mains *b*, then I break contact of the metallic circuit at the point of its said connexion and remove the wires to a corresponding connexion in any other of the boxes *c* along the line of
the mains, and in order that the electric current may not be
4180 induced along to the point so disconnected as aforesaid I
disconnect the said bent end of the wire of one of the poles

of the circuit by detaching the screw before mentioned; the box then may be closed and the ground filled in over it; and so I disconnect and connect at all or any of the points *c* on the mains *b* in any part or parts of said fields or area, and so form at said points metallic circuits and convey electric currents from time to time, when the electro-magnetic force is applied to prevent the collision of trains on railways, reference being had to drawing No. IX and (figure 1, No. 8) elevation and drawing (D and 9 plan). Operation: The metallic circuit being established between the batteries at the stations aforesaid and the electro-magnetic engine on the locomotive through the medium of the electro-magnetic coupling slide as aforesaid, chemical action at said stations being induced and electric currents or influence communicated along the sections of the rails, the electric current may be broken and re-established all along the line at will at the spaces between the sections along the line by well-known methods, and therefore, when from any cause whatever, arising from accident or otherwise, it is desired to stop a train or trains, the batteries being at all times prepared and efficient, the persons charged with the guarding of the railway may at any time establish a metallic circuit between the electro-magnetic br*eak*s aforesaid attach- to the carriages, or any of them, of a train through the medium of the electro-magnetic coupler, which is always in contact with the conducting wires *x* and *x* 1 on the wooden bars *e* and sliding over *x* and *x* 1, the conducting wires leading from the coupler *h h* leading to the poles of the wires round on the magnet, which brings the flexible armature 2, drawing Q P, or armatures with which a lever or levers acting on br*eak*s are connected. The magnet, in drawing the armature 5, which is flexible iron bar, one end at 6 fastened down at that part of the magnet 7 and in contact with it, when the electric current is on or passing through the magnets or helix, moves the lever attached to the armature by flexible rods or cords or wires 1, 2, 3, 4, which
4181 brings the br*eak* or br*eak*s in contact with the wheels of
carriages, and so stop the progress of a train. As the magnet when in action is drawing the armature down upon it by absolute contact of the armature on the magnet, the lines, as it were, of the armature are lines at right angles with the length of the armature and helix, the latter being about two feet six inches long and about six inches wide and the armature of the same length and width and about the eighth of an inch in thickness. When it is desired to release the brak-s from the carriages, the conductors of a train may break the contact of the poles of the wires leading to the magnet or magnets by any convenient means; but when it is desired to prevent the collision of trains, then a battery may be placed on the locomotive carriage D, drawing No. IX in elevation and No. IX A, shown on drawing IX A, at first train or other carriage of the same train. The ends of the wires leading to the electro-magnetic coupler being properly adjusted to the poles of a battery on the locomotive No. IX, the electric current will [illegible] along the railway. If, now, another train, marked 2nd train, drawing IX and IX A, come upon the same section following train No.

IX, then, the coupler h h of the second train being in contact with the wires x and x 1 of the same section, a metallic circuit will be established between the couplers of the two trains from the battery of the train No. IX to the br*eak*s of the second train or the train that has followed and arrived on the same section to the train No. IX. The said *section* train will thus be stopped or impeded until the first train shall have advanced into another section, when the space between the wires x 1 on one section and the wires x 1 on the other section, being broken by the wide space between them, and the wires x 2 and x 3 being always broken at the space and similar spaces, except when it is desired to stop a train from the batteries at the stations aforesaid, the metallic circuit is broken, and can only be again established by the second train again coming on the same section on which the first train may happen to be; thus the collision of trains may be
prevented when the metallic circuits between approaching
4182 trains are properly formed between the battery of engine No.
IX and the coupling rod and br*eak* on a second train; and, further, when the electro-magnetic coupler is on the engine of the second train and the conducting wires m m lead to an electro-magnetic machine on the top of an engine, as at d, drawing No. IX, from whence a cord, passing over a pulley on said electro-magnetic machine, and passes over another pulley or pull*ies*, whence a branch cord from the cord on the pull*ies* leads to the lever, first, on the whistle on the engine, and, second, to a lever on the steam valve of the engine, then when said second train comes upon the same section on which is the engine No. IX and between the battery on No. IX and the electro-magnetic coupler on the engine of the second train and on the same section, and the metallic circuit between said two engines is properly established, the current putting the electro-magnetic engine on said second train in action, the pull*ies* being turned, the said branch cords will pull on the lever of the whistle, and opening it will sound an alarm, and the further movement of the other branch cord will act on the steam valve and shut off the steam. In application of one of said sources of power, namely, the electric power, in any of its forms to one of the things referred to, namely, the electro-magnetic engine, drawing No. X, reference being had to said drawing, the principle of application ha*b*ing already been shown in its application by br*eak*s of carriages on railways. Operation: I effect as one of the common methods of generating said source of power by inducing chemical action in commonly constructed batteries B B, from the poles of which batteries I lead conducting wires to the pedestals C C, in which they terminate in small masses of copper having a smooth horizontal surface. From the poles of the wires wound on the magnets h h h h on the frame a a a a I lead wires to four seperate masses of copper insulated from each other and fixed onto the pedestals C C at c c, having si*n*ilar horizontal surfaces near to the other corresponding masses of copper leading from the poles of the batteries and placed in the
pede*de*stals C C, but made moveable in the following man-
4183 ner: The masses so far apart as completely to break metallic
circuit; the masses of copper at the termination of the wires

leading from the poles of the battery are attached to the lever 1 fixed on its fulcrum 2; at the opposite ends of the lever 1 are balls 3 of greater weight than the masses at the termination of the wires; the masses of copper at the termination of the wires leading from the magnets are attached as aforesaid to the levers 1 in such a manner as that the horizontal surfaces of the masses leading from the poles to the batteries and magnets when brought in contact shall coincide in all parts throughout their surfaces. The method of detaching and bringing in contact the masses of copper connected with the batteries and magnets for breaking and reconnecting the circuit is effected as follows: The masses of copper at the termination of the wires leading from the poles of the battery are raised and depressed by the motion or action of the lever 1, to which they are attached, but the opposite end of the lever being rendered heavier by the balls would tend to keep the masses of copper at the termination of the wires leading from the batteries and magnets always in contact. To effect a separation I employ the following or any other simple mechanical arrangement—that is, I put a spindle, 4, in motion round its axis by means of a band, 5, or any other contrivance, passing over the pull*ies* fixed onto the fly-wheel shaft and spindle. On the spindle 4 I fix a circular cam and to its periphery I fix what I denominate an electro-magnetic hammer by the end of its handle 7, where it forms a hinge joint with the periphery of the cam. By the circular motion of the spindle the cam is turned round, and by its motion the hammer is drawn round the periphery of the cam. The handle of the hammer will rest upon the periphery of the cam on the opposite side to where the masses of copper are placed; when the spindle, in its circular motion towards the masses of copper, brings the hammer beyond its centre of gravity on the side of the spindle next to the masses of copper, it will fall with a stroke of its own gravity upon a projecting flange, *q*, of the masses of copper that are undermost or those leading from the poles of the battery. The combined weights 4184 of the masses of copper and hammer are heavier than the balls at the opposite ends of the lever; hence the masses of copper leading to the poles of the battery will be disconnected from those that are fixed leading to the poles of the magnets and thereby break the connection or metallic circuit. The length of the projecting flange and hammer handle are so arranged as to — the hammer to remain upon the projecting flange for such length of time as shall be necessary to complete the upward motion of that end of the working beam. When the beam is at the top the hammer leaves the projecting flange and the masses of copper are raised upwards by the counterbalancing balls and brought in contact with the masses leading to the poles of the magnets, so that by the arrangement aforesaid, when the parts are properly arranged, the armatures suspended from the beam of the engine may be thrown into and out of power at any desir*e*able and regulated periods. The flexible armature may be formed of thin laminated plates lying on one another so attached to the connecting rods *p p p p* as to allow the plates to slide backwards and forwards upon each other, upon the principle

of a coach spring. The connecting rods *p p p p* are formed in two or more parts. The upper parts *q q* are divided in such a manner as to allow the end of lower parts S S to pass up into the cavity of the divisions, upon the principle of the tubes of a telescope. At the lower end of the division of the upper part *t t t* is a circular ring connecting the division of the upper part through which the under part *u u* passes. Upon a sliding portion of the under part of the connecting rods, as at *v v v v*, are fixed a couple of screw-nuts. These nuts can be moved higher or lower so as to lengthen or shorten the connecting rods at pleasure and so adjust them. The same arrangements as hereinbefore described are made and connected with the other end of the beam on the other side of the engine, — when in action are so arranged as to produce an alternating motion, which is communicated to the crank axle of the fly-wheel by connecting
rods either by the method hereinbefore described or by the
4185 connecting rods K K, a bell-crank action, L. In order to
apply the said source of motive power to the several things hereinbefore described, namely, the electric force of influence by the combination of method and apparatus before mentioned, I further apply the said combination of method and apparatus or some of them to another one of the things referred to in the title of my said patent, namely, to illuminate reflectors or produce lights for lighting said railway or tunnels, or roads or ways or streets, or buildings or mines. To that end I establish the metallic circuits hereinbefore described or similar ones communicating with batteries at similar stations or places as in manner before described, with communicating metallic circuits, which I lead along, through, or to any described places. At such places I construct and fix apparatus into or through which I pass the electric current or concentrate it by well-known common methods, so as on or in said apparatus I *a*ffect by well-known methods or any variation of them what is termed an electric glow or brush, which glow or brush or sparks or heated surfaces being placed in the focus of reflectors yields rays of light, and which reflectors being made to revolve by any of the impelling apparatus hereinbefore described produce revolving lights, which may be used as night signals or signals in tunnels, or which glows being produced by electric effect by known methods, hermetically sealed in glass globes, in which may be placed air or gases or other substances, which may be rarefied or compressed, or in which gases may be generated to increase the illuminating power of the said glow or brush or sparks or heated surfaces, and which globes or apparatus may be placed along roads, streets, buildings, or in mines, into which metallic wires as before arranged may be led and connected and disconnected at fixed points, and to which the electric influence may be communicated from batteries or apparatus at stations aforesaid. Having in my said former specification in the valve main of the gaso-pneumatic railway described a method of unsealing the valve by an electric wire therein
described, I further vary said method by attaching in
4186 the fore part of the locomotive impelling engine or on one of
the carriages of a train a metal bar of the form, when in

elevation, of the metal bar shown in elevation on the driving pulley *s* of the differential railway, the bed being on the lower surface and tapering to a thin edge. The bar being only two inches high, one-half inch thick, and tapering to one-eighth of an inch on the lower edge, on which it is rounded, being then placed on the carriage in advance of the tongue, the lower edge laying along the edge of the valve and on the cemented surface, into which it is slightly pressed, as seen in figure C C C, sectional view, and at *c c*, then being brought in communication with an electric battery, the bar *c* will be heated and the cement will be softened under its contact while moving along the valve.

Claim.

Having set fo*u*rth and described my methods of applying motive power or force or forces to the engines, apparatus, machinery, and the several things and circumstances and shown and described their various applications and uses, I claim the various applications to the uses hereinbefore mentioned and set fo*u*rth and the various methods of combinations, and although the varied combinations of methods and apparatus works, and machinery may be varied in mechanical arrangements, proportions, or quantities to effect the objects or uses herein described, I claim the general arrangements of the methods herein described and combinations aforesaid making up the differential railway described and shown in the drawings No. 1 and 1 A, and the methods and combinations making up the gaso-pnuematic power on canals shown and described in drawing No. 11, and the method and application making up the fire-engine described and shown in drawings No. III, figures 1, 2, 3, and the motion of taking up their source of power from public mains or pipes, and I claim the combinations of method and apparatus making up the impelling steam power on canals described and s*n*own in drawing No. IV. I claim the combination, method, and
4187 apparatus described and shown in drawing No. V, and I
claim the combination of method and apparatus described and shown in drawing No. V A, and I claim the combination of method and apparatus described and shown in drawing No. VI, referred to in other drawings, and the combination of method and apparatus described and shown in drawing No. VII, and the other drawings relating thereto marked No. VIII, and I claim the combinations of method and apparatus described in drawings No. IX and IX A, and I claim the combinations of method and apparatus described and shown in drawing No. X, and I claim the combinations of method and apparatus herein described for putting said engines or similar engines in operation in manufactories or places for manufacturing purposes, and I claim the combination of method and apparatus herein described for applying said electrical currents or influence for the purposes of lighting places.

In witness whereof I, the said Henry Pinkius, have hereunto set my hand and seal the twenty-fourth day of March, in the year of our Lord one thousand eight hundred and forty-one.

H. PINKUS. [L. S.]

And be it remembered that on the twenty-fourth day of. March, in the fourth year of the reign of her majesty Queen Victoria, the said Henry Pinkus came before our said lady the Queen in her chancery and acknowledge- the instrument aforesaid and all and everything therein contained and specified in form above written, and also the instrument aforesaid was stamped according to the tenor of the statute made in the fifty-fifth year of the reign of his late majesty King George the Third.

Inrolled the twenty-fourth day of March, one thousand eight hundred and forty-one.

4188 DEFENDANT'S EXHIBIT STAITE'S ENGLISH PATENT NO. 1222 OF 1848. Mar. 13, '89. W. T. F., N. P. & S. E.

A. D. 1848. No. 12212.

Galvanic Batteries, Magnets, Application of Electricity to Lighting and Signalizing, &c.

Staites' specification.

To all to whom these presents shall come I, William Edwards Staite, of Lombard street, in the city of London, gentleman, send greeting:

Whereas her most excellent majesty Queen Victoria, by her royal letters patent under the great seal of the United Kingdom of Great Britain and Ireland, bearing date at Westminster the 12th day of July, one thousand eight hundred and forty-eight, in the 12th year of her reign, did, for herself, her heirs and successors, give and grant unto me, the said William Edwards Staite, my ex'ors, adm'ors, and assigns, her special license, full power, sole privilege and authority that I, the said William Edwards Staite, my ex'ors, adm'ors, and assigns, or such others as I, the said William Edwards Staite, my ex'ors, adm'ors, or assigns, should at any time agree with, and no others, from time to time and at all times during the term of years therein expressed, should and lawfully might make, use, exercise, and vend within England, Wales, and the town of Berwick-upon-Tweed, and in the islands of Jersey, Guernsey, Alderney, Sark, and Man, and in all her said 4189 majest*ie*'s colonies and plantations abroad, the invention of "improvements in the construction of galvanic batteries, in the formation of magnets, and in the application of electricity and magnetism for the purpose of lighting and signalizing, as also a mode or modes of employing the said galvanic batteries or some of them for the purpose of obtaining chemical products," parts of which improvements have been communicated to me by a foreigner resi*gn*ing abroad, in which letters patent is contained a proviso that I, the said William Edwards Staite, shall cause a particular description of the nature of the said invention and in what manner the same is to be performed by an instrument in writing under my hand and seal to be enrolled in her said majesty's high court of chancery within six calendar months next and immediately after the date of the said in-part-recited letters patent, as in and by the same, reference being thereunto had, will more fully and at large appear:

Now, know ye that, in compliance with the said proviso, I, the said William Edwards Staite, hereby declare that the nature of the said invention and in what manner the same is to be performed are fully ascertained and described in and by the present specification thereof, reference being had to the drawings hereunto annexed—that is to say:

Firstly. My improvements in the construction of galvanic batteries consist in making them on what I call the "perfluent"
4190 system of supply and discharge to contradistinguish it from the "percolating" system, which has recently come into extensive use. According to the percolating system the liquid employed (usually sulphuric acid) is supplied to and discharged from each of the cells of the battery in separate and distinct streams or series of drops, the liquid as it becomes exhausted, though not entirely so, dropping out through an orifice in the bottom of the cell and being then allowed to run to waste, and the place of the discharged liquid being supplied by fresh drops descending from above into each cell; but according to the new system, to which I have given the name of "perfluent," the liquid is supplied in one stream only, which passes continuously through the entire series of cells, entering by the first cell of the series and passing off through the last. The great loss attending the imperfect exhaustion of the portions of liquid discharged from each cell is thus avoided, for the liquid flowing in one stream through the whole of the cells, one after the other, becomes completely exhausted, or as nearly so as may be, before its final discharge from the last of the cells. In ordinary galvanic batteries, where a perforation is made in the partition between any two of the cells so that they may communicate transversely with one another a considerable diminution of electric intensity is known to be the result. That no such diminution is observed to take place in the perfluent battery from bring-
4191 ing the cells into communication with one another owing to the circuitous course it is made to take between cell and cell. In proportion, of course, as the duration of the transit through each cell is shortened the chance must be proportionately lessened for each portion of the liquid coming into contact with the acting metal or element in that cell; yet, as no drop of the fresh liquid supplied to the battery can make its way to the final-discharge outlet without going through the whole of the cells, what it misses in the first cell it is sure to encounter in one or other of the remaining cells. The cells last in order of a perfluent battery necessarily act less powerfully than the earlier cells of the series—as, for example, the last six cells of a series as compared with the first six. The diminution of power—that is to say, the quantity of electricity which the cells are capable of circulating—does not appear, however, to follow exactly in the ratio of the strength of the exciting liquids, for the difference in power between the middle and initial

cells of a series is proportionally not so great as the difference between the middle and the terminal cells. When it is desirable to obtain intensity in the electric current rather than great quantity the terminal cells should be made about equal to the quantitative power of the others by uniting the similar conducting wires of several cells together and using them as if 4192 proceeding from one cell. Thus, as it would be technically expressed, the last three cells in a fifteen-cell battery (say the 15th, 14th, and 13th) might be connected for quantity, and the two next preceding pairs (say the 12th and 11th and 10th and 9th) be con*du*cted also for quantity, and the first eight cells might be worked singly, in the usual manner of a series; but however great may be the differences in power between the initial, middle, and terminal cells of a series, I find that in each cell regarded by itself apart from the others the degree of exhaustion and, consequently, of electric action is always very nearly uniform throughout every part of the cell. In consequence, moreover, of the liquid being in a state of continuous flow and never acting on any one part of the cells more than another, the zinc or other metal employed wears much more evenly than in the percolating battery or any other with which I am acquainted.

The details of a battery constructed on this perfluent principle are represented in figures 1, 2, 3, and 4 of the drawings annexed.

Figure 1 is a view of the battery as seen from above. Figure 2 is a vertical horizontal section. Figure 3 is a view of the trough from beneath, and figure 4 is a vertical section. A is a wooden trough, the parts of which are firmly bolted together. *a a* are slate partitions, the edges of which fit closely into the sides and bot- 4193 tom of the trough and are about two and a half inches apart. *b b* are thicker partitions of wood, which are inserted at short intervals, say every six cells, and made fast to the sides by screws and nuts. *c c'* are two parallel rows of holes made in the bottoms of the cells, two in each. *d d'* are two corresponding rows of wooden covers, which are made fast by marine glue and screws to the bottom of the trough (see figure 3), one underneath each adjoining pair of holes, as *c' c'* or *c' c'*, with the exception of the two end ones, which cover one cell only. *e* is a groove cut out in the upper surface of each cover, and made just of width enough to embrace two of the cell holes, as *c c* or *c' c'*, and so establish a channel of communication between them. *f* is an aperture made in the bottom of the end cover of the series of holes *d* and *f'* a similar aperture in the bottom of the opposite end of the same series of holes, into each of which apertures there is inserted a piece of copper tubing, to which there is attached one end of a flexible hose, *g* or *g'* (made of vulcanized caoutchouc, gutta-percha, or other suitable substance or combination of substances), which terminates at the other end in a funnel, *h* or *h'*, and *i i'* are eyebolts affixed to the ends of the trough on the outside, which respectively sustain in an upright position the funnels *h* and *h'*, there being a slit or opening in the eye of such bolt to admit the neck of the funnel. The whole of the inside of the 4194 trough is well coated with marine glue. The mode of operation with this apparatus is as follows: The liquid is poured in at the funnel *h* and passes into the first cell through the hole *c'* of the cell; from the first cell it goes out through the hole *c* into the first of the grooved covers of the series *d'*, whence it flows into the second cell through the hole *c* of that cell; from the second cell it next passes through the the hole *c* of that cell into the second of the grooved covers of the series *d*, and so on to the end of the series (as indicated by the arrows in figure 1), when it discharges itself through the flexible hose *g'* and funnel *h'* into a receiving vessel, K. The arrangement just described is, however, chiefly suitable for such forms of battery that use but one sort of exciting liquid, but in batteries where two fluids are used, as those of Daniel, Groves, and Callan, it may be expedient to adopt the modification of the perfluent system represented in figures 5, 6, 7, 8, 9, and 10. The internal cells in this case are supposed to be made of earthenware or some other porous material.

Figure 5 is a side view of one of these cells and figure 6 is a vertical section across the middle. A hole is made in the bottom of this cell 2 and into this hole a copper tube, *r*, with a collar and washer of vulcanized caoutchouc at top is dropped. The tube is pulled tightly down upon the washer in order to prevent any of
the liquid escaping between the washer and the bottom of
4195 the cell; or, instead of this arrangement, one of the descrip-
tion represented in figures 7 and 8 may be substituted. S of the description represented in figures 7 and 8 may be substituted. S is a cradle which is cemented onto the under end of the cell by marine glue and encloses it completely. The tube R is screwed onto the bottom of this cradle and through it up to the hole in the cell. In both cases the tube has an oval aperture, *w*, cut transversely through it and terminates at its under end in a solid screw-point. The trough for the reception of porous cells of this description is made in the manner represented at figures 9 and 10, the former being a transverse vertical section of the trough through the centre of one of the cells, and the latter a longitudinal vertical section. In these figures the cradle on the plan, figures 7 and 8, is supposed to be adopted. Q is the internal porous cell and Y the zinc plate suspended therein. X X are the plates of negative surface (say copper), placed outside the porous cell. Z Z Z are the sides and bottom of the trough, the spaces (*m m*) between which the porous cell forms the external cell, which contains the second fluid (say sulphate of copper). A″ is an open channel for the discharge of the second fluid, which runs along the outside of one wall of the trough near to the top, and communicates by lateral apertures (*p p*) in the wall with the spaces inside, *m m*, appropriated to that fluid. V is a grooved or channeled under cover similar to
those employed in the apparatus first before described, which
4196 extends along the bottom of the trough from end to end and
comes immediately under the line of holes in the porous cells (Q). The lower end of the tube *r*, which is attached as aforesaid to the bottom of each porous cell and enclosed by the cradle, is passed downwards through an orifice in the bottom of the trough,

and also through another orifice in the bottom of the under cover V, till the oval aperture *w* in the tube coincides with the groove *t* in the bottom of V, so that when the whole of the cells are fixed in their places the channel *t* forms, through the medium of the apertures *w w*, a common channel of communication between all the cells. U is a nut which takes onto the end of the solid screw-point of the tube *r*, and by turning which the parts S, *r*, V, and Z are all screwed tightly together. For the sake of greater security against leakage and against the intermixture of one of the fluids with the other, washers of vulcanized caoutchouc are inserted between the cradle S and the bottom of the trough and between the bottom of the grooved channel V and the shoulder of the nut U. E is a second under cover which runs parallel to V (on one or either side of it), the groove *e*, in which second cover communicates by a series of holes, *n n*, with the external cells above, containing the second fluid, and thus serves as a common channel through which these cells may be supplied from a flexible hose similar to that before described. The second fluid is, after passing through the external cells, discharged from the ends of the channel A^a. The perfluent
4197 system may be also carried into effect by employing *cyphons*
instead of the grooved under covers (*d d'*, V, and E) before described to transmit the liquid from cell to cell successively, as shown in figure 11, which represents two adjacent cells of a battery. The long end, A, of the *cyphon* descends to near the bottom of one cell in order that it may carry over the densest portion of the liquid therein and deliver it through the short end, B, into the next cell, or if the liquid employed is of such a nature that it becomes lighter as it becomes exhausted (sulphate of copper, for instance), then the legs of the *cyphon* are reversed, the liquid entering it by the short end and being carried over by the long end. By adopting this *cyphon* plan, the breakage or upsetting of one cell of a series will not cause any loss of liquid from the rest, although the liquid will continue at the same time perfluent, nor will the *cyphons* empty themselves until the last portion of liquid is removed from the cells, which need not be done during the time of replenishing or changing the liquids.

The syphon plan just described may be applied with special advantage to a form of battery which has been for some time in use and is represented in figures 12, 13, 14, and 15, with some appendages, however, marked *f*, *g*, *h*, and *i*, which do not belong to this apparatus as originally constructed and hitherto known, inasmuch as that application would convert it at once into a perfluent battery nearly equal to that first hereinbefore described.

4198 Figure 12 is a top plan of this battery, figure 13 a longitudinal vertical section, figure 14 an under view of the trough, and figure 15 a vertical cross-section. In its general construction this battery resembles that first hereinbefore described with the exception that, though all the cells communicate at bottom with one common discharge channel, the liquid does not flow continuously from one cell to another through the whole series, but supposing all the holes in the bottoms of the cells were stopped up and syphons applied to each pair of cells as has been just described, then there would be a continuous flow of the liquid throughout the entire series, from the last of which it might be discharged in an exhausted state by a flexible hose similar to that represented in figure 2.

Secondly. My invention consists of certain improved modes of regulating the supply and discharge of the liquids employed in galvanic batteries.

The first mode which I shall describe will be found particularly applicable to a battery such as that referred to at the close of preceding head of this specification, and consists in using it with the new appendages to it, *f*, *g*, *h*, and *i*, before mentioned and in manner following: In that battery as hitherto constructed the discharge has been effected by the means represented in figures 16 and 17. Into the wooden partition at one end of the trough is imbedded a syphon, *k l*, one leg of which, *k*, opens into the channel *e* and the other
4199 leg, *l*, passes through the bottom of the trough. The short
end of the syphon is made to be on a level with the intended height of the liquid in the trough, and there is a small aperture, *m*, in the highest part of the bend, which communicates with a hole, *n*, cut in the wood, which has a seat around it half way, upon which lies a washer of vulcanized caoutchouc *o*. The broad end of a screw, *p*, screws down onto this seat, presses on the washer and closes the hole air-tight. When the cells are filled up the syphon discharges all the liquid from the channel out of every cell in the trough, and when the screw *p* is turned loose the bent tube *k l* no longer acts as a syphon, but simply discharges liquid as its lever may rise beyond the level of the bend. The fresh liquid is introduced in any convenient manner at the top of each of the cells. When it is desired merely to replenish the exhausted liquid or when it is required to fill up all the cells with fresh liquid after they have been partially emptied the whole quantity of liquid necessary is poured into one of the cells and spreads in equal quantities to every cell. My improvement in this arrangement consists in substituting the flexible hose *g* and funnel *h* and their respective appendages for the discharge cyphon represented in figures 16 and 17 and in working these in the manner to be next described. The flexible hose *g* is lowered as shown in figure 13 at regular intervals of, say, 15, 20, or 30 minutes (according to the quantity of liquid contained in the cells and the rate of action of the elec-
4200 tricity and the degree of steadiness required in the current),
and at each time a portion of the partially used liquid is allowed to run out, after which the hose is raised again and the funnel *h* replaced in its original vertical position, when a quantity of fresh liquid, equal to that which has just been discharged, is poured into the funnel and is conveyed thence into the cells through the common channel *e*. When this battery is so worked the liquid will be always kept about three-fourths exhausted, or nearly so, in which condition the battery may, in some cases, be worked up to about two-thirds of its power. There will always, however, be a

slight waste, as the liquid must, of necessity, be always discharged with about one-fourth of its power unused.

A second mode of supplying the cells has relation to the case in which the liquids become specifically heavier by working the battery (as, for example, dilute sulphuric acid). I cause a constant influx into each cell by means of a pipe or trough extending along the top of the battery having a small orifice over each cell so that the liquid with which the pipe is charged shall drop gradually into each cell, *c*, and the liquid is drawn off from all the cells simultaneously by means of a common under channel, *e*. The funnel or other vessel of supply is fixed in an upright bearing just above the level at which it is intended to keep the liquid inside the cells. By this arrangement all the cells are kept practically at the same level and no attention to each cell separately is requisite.

4201 A third mode of carrying this branch of my invention into effect has relation to liquids which become specifically lighter by the working of the battery (as, for instance, sulphate of copper). The cells are replenished by a continual outflow from a supply vessel fixed at a higher level than the liquid in the cells (similar to A^a in figure 9) through holes or spouts placed at the required level in the sides of each cell. This in practice insures an equal feed for every cell while the battery is working, because if any cell were worse supplied than the rest with fresh liquid from the bottom it would in a short time become more exhausted than the rest, and consequently specifically lighter, which would make it attain a higher hydrostatic level and overflow more abundantly than the others.

A fourth mode has reference to porous-cell batteries and is based on the supposition that the batteries are regularly supplied with liquid. The object in this is to so proportion the supply to the amount of current produced so that any given portion of the liquid (say sulphate of copper solution) supplied to the lower part of one division of each cell shall become exhausted by the time it has worked its way to the surface, when (supposing the solution to have been sulphate of copper it will have become transformed into a clear solution of dilute sulphuric acid) I allow the exhausted 4202 solution to flow over the upper edge of the porous cell into the zinc compartment (instead of drawing it away and supplying the acid to the zinc from another cistern), when this solution becomes gradually charged with zinc and is finally drawn off exhausted a second time from the bottom of the zinc cells by the means pointed out in figure 15 or by any other suitable arrangement.

Thirdly. My invention consists in attaching to all galvanic batteries in which a gradual change of liquid is required an equilibrited hydraulic cistern and graduated meter, such as represented in figures 18 and 19. A is a cask closed at top so as to prevent the free action of the atmospheric pressure on the surface of the liquid contained in it, and *b* is an orifice near to the bottom which opens into a small outer cistern, *c*. This arrangement ensures that the liquid flowing through any channel from the cistern *c* will always

flow at the same rate whether the cistern be full or nearly empty. From this little cistern a loose piece of vulcanized caoutchouc tubing, *d*, proceeds and is connected with the glass tube *e*, from which is suspended the meter *f*, having a small hole at the bottom so that the rate of flow out of this hole is indicated by the height at which the surface of the liquid stands. The meter is graduated to units
to show the amount of flow requisite to supply the chemical
4203 action which is going on in the battery when the electric
current is circulating at a rate indicated by corresponding units on the galvanometer hereinafter described (figure 20), which is included in the circuit. The meter, with its tube *d*, is suspended so as to enable the rate of flow to be adjusted by hanging it at an altered level (in relation to the cistern) according as the galvanometer may indicate to be necessary. The parts *d e* form, in fact, a syphon, which only requires to be filled with liquid when the apparatus is first set in action after the cistern is charged. The liquid issuing from the meter is received by a funnel, *h*, or otherwise led to the battery.

Fourthly. My invention consists in the employment in galvanic batteries having copper or mercury for the negative element of a liquid amalgam of zinc and mercury enclosed in a bag or case of lawn or horse-hair cloth or any other finely reticulated fabric, but not made of metal, which allows of the acid passing freely through its meshes to act on the bottom and sides of the zinc amalgam, which the bag or case retains the amalgam itself. I am aware that a liquid amalgam of zinc and mercury has been before used in place of an amalgamated surface of solid zinc, but to the best of my knowledge never in the way here proposed.

Fifthly. My invention consists in the substitution in galvanic
batteries of solid plates made of an amalgam of zinc and
4204 mercury in the proportion of five parts of the former to one
part of the latter for the zinc plates ordinarily employed.

Sixthly. My invention consists in the employment of lead as the positive element in galvanic batteries (instead of the zinc which is now commonly used) combined with a solution of nitric acid or of acetic acid in some one or other of the forms best calculated to act on the lead. The best negative element in this case would be a surface of platinum, but most of the other negative elements which have been hitherto used may be also employed with the lead.

Seventhly. My invention consists of an improved galvanometer, represented in section, figure 20, which is to be attached to the battery in order to indicate to the eye the exact amount of galvanic electricity which is being circulated at any particular moment. The galvanometers usually employed for measuring the quantity of an electric current are incapable of being used while the battery is applied to perform its work, nor can they indicate the amount of action or electricity circulating while such work is being performed, and these, with several other defects, such as their indications or degrees varying in a different ratio to that of the quantity of electricity passing, cause such galvanometers to be useless for most practical purposes.

My new galvanometer is such that it can be made a per-
4205 manent adjunct to or part of the battery, so as to be always
indicating what amount of electricity is circulating when any sort of duty is being performed by it and the weights of material combining or used per minute at any particular time. The importance of these improvements may be measured by this consideration—that the cost of working a battery depends but little on the size of its elements and varies according to the rate at which its electricity is used by any particular work which it is set to perform. This improved galvanometer consists of a thick piece of insulated copper wire, A, wound round a wooden or brass cylindrical centre fitted with ends, C C. One end of this coil is in metallic connection with the positive or negative pole of the battery, and the other extremity is placed in connection with the part of the lamp (or other piece of mechanism for actuating which the battery is used) which would receive the conductor from the said pole of the battery. In fact, this galvanometer forms part of one of the conductors of the battery which conveys its electricity to perform its assigned work. In the hollow cylindrical centre of the coil there is placed a rod of soft iron, *d*, as shown in the drawing, which moves loosely up and down in it and is prolonged by a short brass stem or index, *e*. A graduated scale, *f*, is fixed to and rises from the upper end, *c*, of the coil, so as to show the height at which the electric influence causes the index to stand. The graduations are represented
in the drawing as marked on a glass tube, within which
4206 the index and rod *d* slide. These graduations are so made
as to indicate the number of grains of pure zinc consumed per minute in each cell of the galvanic series, the current produced by which causes the index to stand at each such division of the scale. Any galvanometer of this kind may be graduated from a standard one by connecting both in the same circuit and by working at Wheatstone's rheostat, also included in the circuit, until the standard galvanometer indicates the particular units or degrees, when a similar mark should be made at the point to which the index is directed on the scale of the other galvanometer. The standard can be graduated by ascertaining, experimentally, the weight of zinc consumed per minute, but a less tedious process is to graduate it from a Petre's galvanometer, which indicates all the required units of electricity and their fractions by means of weights, the accuracy of that instrument being first tested by one such direct experiment on the zinc consumed.

My improved galvanometer may be made of a shorter and thicker wire, making fewer coils, if the iron rod is partially counterpoised by a spring or weights or hydrostatically with mercury.

Eighthly. My invention consists in the formation of magnets in manner following: The best Swedish charcoal iron is to be "converted," not in the ordinary manner, but only a slight carbonization, or what is technically termed carbonizing it "just steel through." The blistered product is then melted and cast and the ingot resulting from the process is rolled out into thick sheet metal.

4207 Ninthly. My invention consists in the following improved mode of hardening magnets previous to magnetizing them: Instead of heating them in an ordinary furnace or sand bath I heat them in a bath of melted metal raised to a red heat (using by preference lead), first polishing the magnets in order to prevent the lead or its oxide from adhering to their surfaces, the heat of the lead being only just sufficient to harden the magnets on taking them out of the bath. I afterwards plunge them into water.

Tenthly. My invention has relation to the mode of obtaining light by electricity, for which I obtain- former letters patent for England and the colonies on the third day of July, one thousand eight hundred and forty-seven, and consists, first of all, in an improved mode of giving motion to the lower electrode. Figures 21 and 22 are representations of a lamp embodying this improvement. The skeleton of this lamp is similar in all respects to that of the lamp represented in the specification of my last patent (that is to say), there is, as before, a foundation plate of wood, A, a sole plate, B, of brass firmly connected by pillars C, and a three-legged stand, K, rising vertically from the sole plate B, the feet of which are fastened to B by nuts beneath, but insulated from it by circular washers of dry hard wood (of the form shown in section *i g*). A hole is bored vertically down through the centre of the top of the stand K, into which hole the upper electrode N is fixed by three metal wedges jambed into keyways or channels sloping upwards and outwards, so as to keep the inner faces of the wedges parallel to the central axis, and a glass shade is fixed to
4208 the sole plate B so as to cover D. The new parts are as follows: H G is a shaft which slides vertically in the central axis of the lamp through holes in A and B and has a socket at top which carries the lower electrodes M. The lower part G is cut with teeth which work into a pinion, F, which turns on a spindle in fixed supports. A barrel, F′, is attached to the pinion F and a weight, W, is suspended by a string which passes round F′ and is fixed to it so as to counterpoise the weight of H G. On the spindle of the pinion F is fixed a wheel, E, having square teeth. A lever, T, turns loose on the same spindle as a fulcrum, and carries a double paul, U V, which turns on a pin which projects from the side of T, so that this paul U V can lock into the teeth of the wheel E in either direction. A long horizontal lever, Q, passes over this paul from a joint or fulcrum, *a*, and this lever carries a light spring or tongue, *b*, close beneath it, the end of which is kept from springing away from the lever by resting in a step in a little stirrup or fork, *d*, which is attached to the lever Q and embraces the wheel E and the end V of the paul. The paul and its lever T are kept in a state of slow vibration from side to side by means of a crank, S, which works in a fork at the end of T, the crank S being made to revolve by an ordinary train of wheel-work enclosed in a case, A^2, furnished with an escapement or fly wheel and driven by spring power or weight. When the lever Q is turned a little downwards its tongue *b* presses V into the teeth of the wheel E and the vibration motion

of T causes V to drive the wheel round notch by notch. The 4209 wheel does not follow the paul in its back motion at every stroke, for this is better ensured by having a spring, *n* (Fig. 22), fixed to A and pressing against the side of G. This motion of the wheel causes the pinion to elevate the rack G slowly, so as to raise its electrode M towards N. But when the lever Q is raised or turned upwards the notch in the stirrup lifts the tongue *b* off V and allows U, the heaviest end of the paul, to drop into the teeth of the wheel E. This drives it round in a contrary direction so as to lower the rack F and draw its electrode M further from N. Whenever the lever Q is raised the lower step in the stirrup *d* catches the sides V and draws it (V) up out of the teeth of the wheel in case V should have become jambed or hitched in the teeth, so that the counter-weight of U might be unable to release it. The means *of* which the end of the lever Q is raised or lowered are these: R is a regulator coil such as is described in the specification of my last patent. One end of its wire is connected with a binding screw, *e*, and the other end L is brought up and fixed in contact with K. An iron rod, O, moves freely up and down in the central hole of the coil, and is prolonged upwards by a stem of wood, *p*, by which it hangs to the end of the lever Q in the manner shown in the drawings (figures 21 and 22). The rod O passes through a hole in the centre of a cup, *y*, which screws into the bottom of the coil case. Around O there is a circular weight, X, called an equilibrium weight, which rests on a small step in O when O is raised, and when O sinks below its medium position is left behind resting on the edge of rim of *y*. The object of this arrangement 4210 is that when O is actuated by a force equal to its own weight added to half the weight of X, then it will have a tendency to return to its medium position with a force of half the weight of X, whether it be raised higher or sunk lower than that position. The mode of action is as follows: The end of the negative wire from the battery is set in the binding screw *f* and is conducted thence by a metal connection to the supports of the spindle of the pinion and to the spring *n*. The current passes through these into the rack; thence to the lower electrode M from which it passes to the upper one N producing the light between them. From N it proceeds through the stud K to the wire L of the regulator; thence to the clamp *e*, which is in connection with the other end of the regulator wire and into which the positive wire from the battery is clamped to complete the electric circuit. The current in passing through the regulator tends to raise the iron centre O, which, being connected to the lever Q, is counterpoised to the weight W′, which screws along an extension of the lever beyond the fulcrum *a*. To put the lamp into adjustment, the driving gear, being wound up and the battery being in a state of activity fit for the permanent action intended to produce the light and its wires connected with *e* and *f*, as described in lever Q, is raised by hand until the electrodes have separated to the greatest extent compatible with obtaining a permanent light from them. The screwed weight W′ is turned backwards or

forwards until it keeps O balanced just so as not to sink be-
4211 low its medium position when the electrodes are separated as
aforesaid. When in this position the shoulder of O touches the weight X, which is resting on the rim of *y*. The lever Q carries a little projecting piece or catch, *g*, which meets the bent arms attached to the crank spindle S, and thus arrests the motion of the crank, when the lever lies so that O is in its medium position; but whenever it rises above or sinks below that point the catch *g* allows *h h* to pass beneath or over it accordingly, so that the crank can revolve freely and work the ratchet U V.

Another improvement in the lamp consists in subsituting for the upper electrode previously employed a disc or circular electrode fixed on an axis, which disc has a slow motion imparted to it in any given direction by the moving power employed in the lamp. Impinging on the periphery of this disc there is a metal scraper, which keeps the edge of the disc clean and free from the particles of carbon which are projected upon it by the other electrode and which ordinarily collects in the shape of a button on the point of the electrode. A front view of a lamp on this plan is given in figure 23 and a side or edge view in figure 24. A' is the disc which is shown in section in figure 24; it resembles in its form two cones
placed base to base, so that there is always one sharp or feather
4212 edge in sight (so to speak) of the negative electrode, which is
of the ordinary single cone form. B' is the scraper. B^2 is a frame which carries the shaft C^2, to which the disc electrode A' is attached. D^2 and E^2 are a bevelled wheel and pinion which gear into one another, the latter being fixed to the shaft G^2. At the bottom of this shaft there is another wheel, H^2, to which the clock-work or other apparatus for giving motion is attached. The shaft G^2 may be insulated in various ways either by the interposition of plates of ivory or wood (J K) screwed together or by gutta-percha or India-rubber rings. Instead of the shaft G^2 and the wheel and pinion D^2 and E^2 a metallic chain may be used working over a pulley or pulleys, the object being to give a very slow motion only (say one revolution an hour) to the circular disc of carbon and for the purpose solely of keeping the edge of the disc sharp and free from the projected particles as described.

Another improvement consists in the employment of iridium as an electrode which is suitable for smaller lights. Iridium, being of all known metals the hardest and most intractable, will bear an excessive degree of heat without fusing. To adapt it for electrodes I prepare it as follows: I fuse oxide of the metal in a cupel of bone ash under the voltaic arc, by which means it is brought under the action of the most intense heat with which we are acquainted. Having obtained an ingot
of the metal, I submit the same to the constant action of heat
4213 for the purpose of annealing it, and for this purpose I use
one or more large jets from an oxyhydrogen blow-pipe. When the ingot is at a white heat I pass it between rollers or hammer it, repeating the process again and again until the metal is sufficiently annealed to be worked up into the required shape. Sometimes I mix platinum with the iridium and sometimes copper

in small quantities, which facilitates the annealing. Sometimes also I cut it into thin strips from the ingot in the same way as precious stones are cut by the lapidary. For lighting purposes I use either a thin strip of the iridium so prepared and cut off or a combination of iridium with platinum or of iridium with copper or a spiral coil of the iridium as a solid electrode. Platinum strips and platinum wire have been used before and are well known, but iridium so prepared has never, to the best of my knowledge, been before used for the purposes of lighting. To increase the temperature of the metallic electrode A′ I sometimes pass the metallic holders B B through a block of glass, D D D, or other similar bad conductor of heat (as represented in figure 25), so that the heat and radiant light may be developed with as little loss of the former as possible by radiation.

An elevation of a small iridium bracket lamp is given in figure-25*a* & 25*b*. A′ is the electrode of iridium which is fused on or otherwise fixed to two pieces of platinum B B which are fixed into two copper or other metallic holders C C. These holes 4214 are insulated by means of ivory wood or vulcanized India-rubber washers D D or some suitable non-conducting substance so as to prevent contact with the bottom metal plate of the lamp E. To one of the metallic holders a copper wire (*a*′) passing through the hollow tube B′ is connected with one pole of the battery, and the electric circuit is completed and the current made to pass through the brass-work of the lamp to the electrode by turning the ivory knob X which is attached to a screw-shank, Z, making a metallic communication with the other holder. The second wire from the battery may be attached to any part of the lamp or socket, as, for instance, by the binding screw W. Y is a ring of brass which is screwed into the bottom of the lamp. A glass shade of any shape or form may be placed on the plate E.

Figure 26 represents a triple electrode suspending lamp. Each electrode is independent of the others and insulated as before. A battery for working this lamp is divided into three parts, one for each electrode. One wire for the return current (which may be fixed to the lamp or any part of the metallic tube by which it is suspended) is sufficient for all three electrodes, but each electrode is rendered luminous by completing the circuit of that particular electrode as before described. A A A (figure 26) are three way knobs with metallic shanks for making the necessary communication, as before described.

Eleventh. My invention consists of certain arrangements for producing a regular intermittent light from electricity, which are especially suitable for light-houses and may also be applied to other purposes. An apparatus embodying the chief of these arrange- 4215 ments is represented in figure 27. The parts in this apparatus which are similar to those in the permanent-light apparatus, figures 21 and 22, before described, are indicated by similar letters. A helix coil of insulated copper wire, A, is employed for the purpose of producing the prime moving force which actuates the sliding shaft which holds the electrode. This helix is fixed to the bottom

of the frame-work C C′ C″. It is nearly of the same construction as the regulator coil before described, only it is a little longer, and instead of being used to regulate the occasions and degree of action of some other moving force it produces the moving force itself, and the number of concentric coils of wire varies at different parts of its length. A cylinder of soft iron, B, moves freely up and down in it. To the top of B is fixed the rack E, which slides through the hole at C″ and carries the electrode M, fixed in a socket, so that this shaft can move the electrode M to or from the lower end of the electrode N, which is fixed in the top of the tripod K by wedges or screws. K is fixed and furnished in the same manner as that shewn in figure 21 and before described. The weight of the shaft B E is rather overbalanced by the weight Q, which is attached by a string passing over a pulley, R to B. A pinion, F, works into the rack E and fits it loosely, with a "back lash" of about a tenth of an inch; or, instead of this pinion, may fit loose around its spindle, which may have a key or feather fixed on the spindle, working loosely (to the extent of an arc $\frac{1}{10}$ inch at the circumference) in a "keyway" in the pinion. The pinion F is connected with an ordinary train of multiplying wheel-work (concealed behind the brass plate
4216 C‴) and terminating by any well-known sort of fly or escapement motion of such kind that F will be prevented from revolving quickly, but will, at the same time, yield with a slow motion to any slight force from the rack E, so as to prevent the rack E from moving up or down too quickly. The negative wire *a* from the galvanic battery is connected with one end of the helix coil A, and the other end of it is soldered to the brass case, so that the current passes through the helix wire to its case, and thence, by means of the springs D D, which are fixed to the case and are in contact with the iron cylinder B, up the shaft D E to the electrode M, whence it flows through N, down K, and returns to the positive pole of the battery by means of the wire *y*. But when the current thus passes the helix A causes the shaft B to be drawn downwards, which motion separates the two electrodes M N, and light is evolved until the electrodes become too far separated, when the current suddenly ceases, the light becomes extinguished, and the helix ceases to draw B downwards, when the weight Q begins to draw it upwards again until the electrodes touch one another, whereby the electric current is re-established and the light is repeated as before. The slow gear and pinion motion used in the above apparatus may be dispensed with, and then it will produce a series of flashes of light at shorter intervals; or, instead of the pinion F fitting the rack with a "back lash" or being loosely keyed on the spindle, it may be placed on its spindle so as to revolve free upon it and the addition of a circular rack on the side or in the central hole of the pinion with a spring ratchet fixed to the spindle in such position as to work into the said circular rack. An opposite
4217 arrangement of the rack and spring ra-chet will cause the pinion to move quickly to one direction (for the electrode shaft E to move downwards) without the spindle turning with it, and the ratchet will prevent the reverse motion from being made

quicker than the slow-motion gear will admit of. This will cause a brief flash of light with intervals of darkness of any desired duration, or, thirdly, the electrode shaft may work two pinions, each working in a separate rack on opposite sides of the shaft or both on the same rack, each of them turning freely on their spindles in one direction, and the direction being different with each, each two being caught and made to turn its spindle with it when turned in its opposite direction. These pinions are each connected with a separate (or partially separate) slow-motion gearing, as before described. This will make both the flashes and the intervals of darkness to be of any desired duration. These intermittent lights are convenient applications of the electric light when it is desired to have an apparatus requiring little expense and attention, partly because by this arrangement an electrode of moderate length may be made to last a long time. An especial advantage is this when the light is fixed on a stand upon a rock, for instance, at some distance from any spot on which a light-house of the ordinary description could be built, and where consequently the battery is on shore or at a considerable distance and communicates with the lamp by
means of wires insulated after the manner of submarine
4218 telegraph wires and buried in the sand or cemented between
the rocks, and where with this arrangement the lamp itself may be difficult of access in stormy weather and require to remain in a good working state without new electrodes for some days together.

The apparatuses which have been described, figure 27, may be modified in manner following as to produce also a good permanent light. The helix A is made sufficiently powerful (more so than is necessary for the intermittent light), and the weight is so adjusted that it shall be balanced by the force of the helix acting on B just when the electrodes are not so far apart as to endanger the continuity of the light nor closer together than about one-quarter of the diameter of the lower electrode M. A chain is hung from the weight Q, with its end resting loosely on the stand C, and this chain is equal in weight to a similar length of the electrode M, so that as the electrode wears away the diminution of weight is just compensated and the weight of the shaft remains properly balanced. In this modification of the apparatus the rack and its slow-motion pinion are made to work smoothly together without any back lash or looseness of pinion on its spindle.

Another means of modifying the said apparatus, figure 27, to produce a permanent light is to fix a regulating coil with a properly weighted iron centre, &c., just like that described in figure 21 (at R *o*
p X *y*). This coil is fixed to C, figure 27, and its wire is per-
4219 manently included in the electric circuit, and instead of
P moving a ratchet, V V, when it drops, it presses a spring or lever in connection with the negative wire from the battery into contact with the shaft B, so that most of the electric current passes from the negative wire through the lever to B direct and B is no longer drawn down by the action of A, but begins to rise by the force of the weight Q, which in this modification of the apparatus

is made to overbalance the shaft as it does in figure 27. Hence this arrangement will preserve the electrodes from approaching too near or receding too far while the electric current is continued in action. The apparatus employed, figure 27, in any of the preceding modifications may be made to act by substituting the arrangement shown in figure 28 for the parts A and B, which gives a greater moving power and allows the electrode shaft to move through a long space, not limited by the length of the coil A.

A′, figure 28, is a helix coil similar in construction to A, but differing in form, as is indicated in the sectional view, figure 28. A short hollow cylinder, B′, is substituted for B; a brass rod, B″ (or a bar "feather-edged" for the sake of lightness), passes freely through B′ and ratchet teeth are cut in it, as shown, by which a spring ratchet, *q*, suspends B′ in the position shown in the drawing. An end, H, which screws onto the top of the central tube of the coil A carries the conducting springs D D, and guides the shaft B″. When
4220 the shaft B″ rises (carrying B′ with it) it brings the projecting end of the ratchet *q* against the slanting side of H, the pressure of which pushes the ratchet out of the teeth and lets B′ descend for the space of one notch or tooth, so that B′ is always ready when the current in A′ acts to draw the shaft B″ a fraction of an inch lower and yet does not prevent the shaft from gradually moving upwards to any extent to supply the waste of the electrode, while B′ never follows the shaft higher than H. The helix coil last described (figure 28) may have its action on B′ augmented by making certain parts of the case in which the coil is wound to be of soft iron in place of brass, as shown by the section of the case in figure 29, the parts marked *a* being iron and *b* brass. The exterior circumference of the case is also cooped round with bits of iron fitting round the case like the staves of a cask, bands of vulcanized caoutchouc being placed around them to keep them together; or a cylinder of iron may be slipped over the end of the coil and envelope it. These pieces of iron augment the magnetic power of the other parts in several ways, and the main result is magnetic attraction between the lower end of B′ and the ends of iron which project upwards from the lower end of the central hole in the helix case. An electro-magnet may be used in place of the said helix coil surrounding the moving piece of iron B′, the poles of the electro-magnet being presented obliquely or directly beneath B′ and the form of B′ being altered so as to be the better suited to be attracted by both poles of the electro-magnet.

4221 Reflectors may be adapted to electric light-house lamps as well as to electric lamps of all sorts. I prefer the arrangement for this purpose shown in section by dotted lines in figure 27. Portions of the reflectors are placed inside the glass bell or shade and supported by projections from the tripod, and their continuation is effected by a separate piece properly placed around the shade or they may be supported by wires branching from a ring which fits around the base of the glass shade. The form of these reflectors is described by the revolution of a hyperbola about its focal ordinate, which is coincident with the axis of the electrodes, the asymptotal plane of the hyperboloidal surfaces being at such an angle as will give a convenient amount of dispersion vertically to the horizontal sheet of light which they will produce, so that a slight variation in the height of the luminous focus will be of little moment by reason of the extent of the vertical dispersion.

Twelfthly. My invention consists in improving by the means following the intensity of the electric currents (whatever may be the nature of the lamp or apparatus used for producing the light). I effect this by including in the electric circuit a long coil of insulated copper ribbon wound in an iron case (such as shown in section, figure 30) and part side view with the cover removed in figure 31, whereby I am enabled at the same time to reduce the number of cells employed. The coil may be made in pieces separately
4222 wound on and their ends joined in succession, the two extreme ends, A *e*, of the first and last coils being made to pass through the holes *p q* in the case. A hollow cylinder of iron or a number of bits of flat iron bar, *g h*, are placed around the coil like the staves of a cask and are held together by elastic bands of vulcanized caoutchouc. A good proportion of the substance of the coil is $\frac{1}{100}$ of a square inch of copper in section to every forty yards of length. The ends of each coil are held from slipping back or unwinding while the next coil is being wound by being bent round and backwards over a pin, K K′, screwed into the side of the iron case. The numbers annexed to the arrows indicate the succession of the different portions of the coil on which they are placed. The letters A B C D E indicate the commencement of each of the coils and *a b c d e* their several terminations.

Thirteenthly. My invention consists in enclosing the solid electrodes employed in electric lamps in supporting tubes as represented in figures 32, 33, and 34. When the electrodes are required to last for a long time they have to be longer than is convenient for their strength or for the proper conduction of the electric current. I therefore use a tube, *e*, which serves to guard the electrodes to hold them steady, and to conduct the electricity freely up to the top part of the electrode, the current being passed into the tube through the sole plate *c″* which is put in metallic connection with the negative wire D″ D″.
4223 Figures 32, 33, and 34 are conductors (they may be of iron) fixed on the tube *e*, the tips of which embrace the electrode near the point where the light is developed. The electricity has by this means a free passage from the tube into the electrode. The tube may be fixed mechanically to the frame-work *c c″* and yet insulated electrically from it, as is shown in figure 33, by means of collars of dry hard wood *z z* on the same principle as the legs of the upper electrode stand K are insulated from the sole plate *c″*. The electrode may be composed of many pieces slightly joined together end to end and placed in a tube, figure 34, of any required length. To obviate the necessity of joining the parts firmly, the following arrangement, figure 34, is contrived, wherein the electrodes need never be drawn backwards in the tube. *c″*, figure 34, is a piece of the supporting frame-work of the lamp, made for the purpose of holding the tube steady. The tube has a free sliding motion for a

short space that is upwards until the nut f touches the under side of z^3 and downwards until the collar f' touches the upper side of z^3 (or, rather, until it touches the part q which rests on z^3). The weight of the tube is nearly counterpoised by the elasticity of the spring q', which is attached to an arm projecting from the tube, as shown, and has an arm, q, fixed to its other end, the further end, q, being forked so as to embrace the tube and to rest the pressure of the spring upon the top of z^3. The weight of the tube being thus supported, it rises with the electrode when it is pushed upwards by E' 4224 until f touches z^3, and after that the electrode rises by passing through the tube. The parts of the fixed supports $c\ c''$ through which the tube passes may be insulated from the rest of the frame-work by collars of wood, as represented by $z^2\ z^3$.

Fourteenthly. My invention consists in the following improved modes of preparing the materials for electrodes: I take the powder of various carbonaceous matters which make electrodes, of different qualities as to illuminating power and resistance to abrasion by the electric current. The materials preferred are, first, plumbago powder, having its iron, &c., extracted by washing and warming in acids; second, lamp-black; third, charcoal powder of sundry kinds of wood; fourth, the powder of carbonaceous concrete, which becomes deposited in gas retorts; or, fifth, grains of this latter substance sifted so as to obtain a somewhat uniform size of grain. Any one of these materials I mix with a quantity of brown sugar in such proportions as are requisite to form a free paste with the powder when the mixture is melted by heat, a much larger proportion being sometimes employed for making the product cohere better. This mixture is melted and boiled (without water) until it becomes stiff. It is then pressed (while hot) into iron moulds of suitable shapes, the inside being lined with paper or chalk or plaster of paris to prevent the mixture from adhering to the mould and to form a porous envelope through which the gases, &c., can slowly escape. The moulds have 4225 numerous small crevices or holes for the purpose of letting the gases and steam escape from the material when baked. The moulds when charged and closed tightly are heated very gradually so as to allow sufficient time for drying it and dispelling the gases without their d*i*stroying the compactness of the material. When a red heat is thus obtained it is after a time allowed to subside, when the contents of the moulds are carefully taken out and placed upright in a crucible which is filled with sand luted down and gradually raised to a white heat. At this high temperature they may be kept for some time to give them greater mechanical hardness and strength; they are then covered up and allowed to cool gently, and, being cleaned if they retain a coating of any other substance, they are put into close-fitting tin cases for use. I preserve these electrodes from becoming damp or otherwise injured by coating them with tin-foil. In some cases also I prepare electrodes for use by wrapping them tightly in several thicknesses of metal foil, such as tin, for the purpose of giving them greater strength and making them better conductors. Good electrodes may some-

times be cut out of a lump of plumbago, either natural- or artificially compressed from the powder. Before using the electrodes it is sometimes beneficial to prevent the liability of their cracking when they become suddenly heated; this is done by fixing them in the lamp ready to light and then passing the electricity
4226 through them without allowing the machinery to separate
their extremities: this heats them gradually and drives off any damp that may be in them.

Lastly, my invention consists in the employment of galvanic batteries for the purpose of obtaining various chemical products, and this either in conjunction with the employment of them for lighting and motive purposes or as substitutes for the ordinary processes of chemical manufacture. The batteries should be of one or other of the perfluent sorts hereinbefore described on account of the facilities which they afford for drawing off the products of the galvanic action, which products may consist either of matters in a marketable state or which require some additional treatment to make them of commercial value. The elements proper to be employed will vary in each case with the chemical product or products desired to be obtained or, to state the matter conversely, the perfluent products will vary with the elements employed; for example, where juice is used for the positive metal with sulphuric acid sulphate of zinc is formed; but sulphate of zinc in large quantities would not be of great commercial value. When, therefore, I use zinc as aforesaid, I collect the sulphate of zinc and treat it as follows: I add in a separate vessel to the solution of sulphate of zinc a solution of sesquicarbonate of ammonia which precipitates the oxide of the (metal zinc) and releases the acid which may be used again. This oxide of zinc is a valuable substitute for
4227 carbonate of lead as a pigment and may be used extensively for painting purposes. Again, suppose any of the salts of lead are required to be produced, such as nitrate of lead (white lead) or sulphate of lead or any other chemical substance to the production of which these salts may be auxiliary, the battery should be constructed of lead or other metal plates platinized and excited to action by dilute nitric acid. The acid acting on the oxide of lead formed by the electrolytic process or decomposition of water dissolves it and forms with it a solution of the nitrate of lead, and this solution is afterwards treated in a separate vessel or vessels with the carbonate or bicarbonate of potash, when a double decomposition takes place and, the carbonate of lead being precipitated, the matter of commerce remains in solution and is obtained by evaporation. Supposing, further, the platinized plates of (lead or other metal) are used with muriatic acid (dilute or not), then the acid is decomposed and a solution of chloride of lead is the resulting product. If for the platinized plates we substitute iron or zinc plates the chloride of iron or of zinc is respectively obtained. Should a battery of copper and of iron plates charged with a solution of sulphate of copper be employed the iron is oxidized and sulphuric acid unites with the oxide by superior affinity and forms with it sulphate of iron (the green copperas of commerce), which remains in

solution and may be obtained by evaporation as before. The hydrogen which is released goes to the other pole—that is, to
4228 the copper plate—and, meeting there the disengaged oxide of copper, reduces it to the metallic state, and, in fact, plates the copper with it. This form of battery is directly applicable to the production of metallic copper from the ores of the sulphuret decomposed by water or from the water drawn from certain copper mines which contain sulphate of copper in solution. The sulphate of iron obtained forms also a very fine ocher.

And having now described the nature of my invention in the several parts thereof and in what manner the same is to be performed, I declare that the improvements that I claim are as follows:

First. I claim the construction of galvanized batteries on the perfluent principle before explained and illustrated, whether the perfluence of the liquid is effected by means of intercommunicating channels at the bottom of the trough or by syphons at top or by any other equivalent means.

Second. I claim the employment, in galvanic batteries, of flexible hose, with funnels attached thereto, to charge and discharge the cells, as before described.

Thirdly. I claim the construction of the double-fluid battery before described, so as to cause the perfluence of two separate and distinct exciting liquids, as hereinbefore described.

Fourthly. I claim the equilibrated hydrostatic cistern for the purpose of supplying galvanic batteries, as before described.

Fifthly. I claim the graduated metre to be attached to a
4229 cistern or supply vessel for the purpose of regulating or adjusting the quantity of exciting fluid which may be intended to pass through the battery, as before described.

Sixthly. I claim the mode of enclosing a liquid mercurial amalgam of zinc in a bag of lawn or horse-hair cloth or other finely reticulated fabric for the purpose of being used in lieu of the amalgamated zinc plates or rods of galvanic batteries, as before described.

Seventhly. I claim the amalgam of zinc and mercury in the proportions and for the purpose hereinbefore described.

Eighthly. I claim the combination of lead (instead of zinc) as the positive element with any suitable negative element and with nitric acid as the exciting fluid in galvanic batteries, as hereinbefore described.

Ninthly. I claim the improved galvanometer and graduated scale, hereinbefore described.

Tenthly. I claim the several improvements in the formation of magnets, before described.

Eleventhly. I claim the several improved modes of actuating the electrodes in electric lamps represented in figures 21 and 22, as hereinbefore described.

Twelfthly. I claim the improved regulator for electric lamps (shown in figures 21 and 22), and hereinbefore described.

Thirteenthly. I claim the revolving circular electrode with con-

ical edges in combination with an edge scraper for electric
4230 lamps, as before described.

Fourteenthly. I claim the mode of making the electrodes of electric lamps of iridium and alloys of iridium in manner and for the purposes hereinbefore described.

Fifteenthly. I claim the employment in electric lamps of glass or other similar imperfect conductor of heat to envelope the metallic holder to which the electrode is attached, as hereinbefore described.

Sixteenthly. I claim the enclosing of the electrodes of electric lamps in supporting tubes and the making them in pieces, as before described.

Seventeenthly. I claim the insulation of the said electrode tubes from the metal stand in manner before described, so as to allow of two or more separate lights being worked with separate currents of electricity independently of each other, but near together and under one glass shade.

Eighteenthly. I claim the several arrangements for producing a regularly intermittent light from electricity suitable for light-houses, as before described, and the various modifications by which the same may be adapted to the production of a permanent light, as before described.

Nineteenthly. I claim the combination of an intensity coil, shown in figures 30 and 31, with a galvanic battery, in manner and for the purposes hereinbefore described.

And, lastly, I claim in the formation of galvanic batteries
4231 for the purpose of obtaining products the several combinations of galvanic elements and exciting fluids, as hereinbefore described.

In witness whereof I, the said William Edwards Staite, have hereunto set my hand and seal this twelfth day of January, in the year of our Lord one thousand eight hundred and forty-nine.

W. E. STAITE. [L. S.]

And be it remembered that on the twelfth day of January, in the year of our Lord 1849, the aforesaid William Edwards Staite came before our said lady, the Queen, in her chancery and acknowleged the specification aforesaid and all and everything therein contained and specified in form above written, and also the specification aforesaid was stamped according to the tenor of the statute made for that purpose.

Enrolled the twelfth day of January, in the year of our Lord one thousand eight hundred and forty-nine.

4241 DEF'T'S EXHIBIT DE MOLEYNS' ENGLISH PATENT NO. 9053 OF 1841. Mar. 13, '89. W. T. F., S. P. & S. E.

(Third edition.)

[British coat of arms.]

A. D. 1841. No. 9053.

Specification of Frederick De Moleyns.

Production or development of electricity and its application to illuminating and motive purposes.

London: Published and sold at the patent office sale branch, 38 Cursitor street, Chancery lane, E. C. 1886. Price, 11d.

4242 (Third edition.)

A. D. 1841. No. 9053.

Production or Development of Electricity and Its Application to Illuminating and Motive Purposes.

De Moleyns' specification.

To all to whom these presents shall come I, Frederick De Moleyns, of Cheltenham, in the county of Gloucester, Esquire, send greeting:

Whereas her most excellent majesty Queen Victoria by her letters patent under the great seal of Great Britain bearing date at Westminster the twenty-first day of August 1841 in the fifth year of her reign did give and grant unto me the said Frederick De Moleyns my ex'ors adm'ors and assigns her especial licence full power sole privilege and authority that I the said Frederick De Moleyns my ex'ors adm'ors and assigns or such others as I the said Frederick De Moleyns my ex'ors adm'ors and assigns should at any time agree with and no others from time to time and at all times thereafter during the term of years therein mentioned should and lawfully might take use exercise and vend within that part of the United Kingdom of Great Britain and Ireland called England the dominion of Wales, and town of Berwick-upon-Tweed my invention being "certain improvements in the production or development of electricity and the application of electricity for the obtainment of illunation and motion" in which said letters patent there is contained a proviso that I the said Frederick De Moleyns shall particularly describe and ascertain the nature of my said invention and in what manner the same is to be performed by an instrument in writing under my hand and seal to be inrolled in her majesty's high 4243 court of chancery within six calendar months next and immediately after the date of the said in-part-recited letters patent as reference being thereunto had will more fully and at large appear.

Now know ye that in compliance with the said proviso I the said Frederick De Moleyns do hereby declare the nature of my invention and the manner in which the same is to be performed is particularly described and ascertained in and by the following instrument in writing

My improvements as embraced by the title of the said letters patent may be resolved into three branches namely improvements in the production or development of electricity by certain novel combinations of known substances whereby the electric power is largely developed by small quantities and superficies of those substances with the important advantages of nearly perfect freedom from the noxious effluvia arising from certain combinations previously known avoidance of the use of mercury and of undiluted acids and the preservation of equal power for a long period—Secondly the application of the electric power or principle whether produced by the improved combinations above referred to or by previously known combinations to a new and improved mode of producing what is commonly called "electric light" whereby that light may be sustained and increased so as to make it available for lighting apartments or for any other illuminating purpose—Thirdly improvements in the application of electricity in its voltaic form when developing magnetic power in iron to the production of a motive force of increased effect by means of improved modes of producing magnetism in iron and of arranging and combining the electro magnets—For convenience I shall describe my improvements in each branch separately but before detailing the nature of those relating to the production of electricity I will recount briefly the most approved combinations hitherto known and publicly used in order that the improvements and modifications effected by me may be the more readily comprehended and distinguished Electricity as produced by metallic combination with fluids was first developed in quantity by the pile of volta which consisted of two metals with moistened flannel interposed and piled in series—Cruikshanks and Wollastons batteries succeeded at intervals which were troughs divided into compartments—acidulated water being interposed between the zinc and copper—the difference between the latter and former being that in Wollastons battery both sides of the zinc are brought into action by being surrounded by copper whereas in Cruikshanks only one side of the zinc had a copper surface opposed—These batteries variously modified by Hare Faraday and others were in general use in Great Britain until 1836 but the powers of all diminished greatly after a few minutes
4244 which limited their application to scientific research—In 1829—Becquerel of Paris discovered the possibility of obtaining a constant current by the use of two metals and two fluids with a diaphragm interposed and his voltaic combination consisted of a solution of nitrate or other salt of copper in contact with the copper separated by a diaphragm of animal membrane or plaster of Paris from a solution of sulphate of zinc in contact with the zinc The diaphragm prevented the adhesion of positive elements to the negative surface and the nascent hydrogen was removed by deoxydating

copper—This grand discovery laid the foundation of various modifications and improvements subsequently effected in the voltaic battery—In 1836 Daniel's constant and Mullin's sustaining batteries were brought forward both being similar in principle to Becquerel's in the use of two fluids two metals and the diaphragm the fluids in Daniels being solution of sulphate of copper and acidulated water with amalgamated zinc and copper the fluids in Mullin's being a weak solution of muriate of ammonia (the use of which obviated the necessity of amalgamating the zinc and using acids) sulphate of copper in solution zinc and copper—In 1838 Grove introduced the nitric acid battery which consisted of platina in undiluted nitric acid both being contained in a porous diaphragm amalgamated zinc and water acidulated with sulphuric acid This the most powerful combination of any hitherto known is not fitted for extensive use by reason of the noxious fumes arising from the decomposition of the nitric acid—the inconvenience in the use of the acid itself—the impossibility of preserving an equally powerful current for a long period and the use of mercury in amalgamating the zinc It now only remains to describe the combination I have discovered which obviates the greater part of the inconveniences arising from the use of other batteries and at the same time developes extraordinary power To one pound of nitrate ammonia I add twelve fluid ounces of soft water and as soon as the salt has fully dissolved I add to one measure thereof the like quantity of pure sulphuric acid of commerce taking the precaution to place the vessel containing the solution in ice or salt and water or some other frigorific mixture and gradually introducing the acid so as to prevent the mixture from attaining a high temperature—the fluid is to be stirred as the acid is poured in—and as soon as the preparation above named has been added the vessel is to be placed in a cool place until the liquor becomes cold—it is then to be put into stoppered bottles and is fit for use it may be well to observe that as what is called the pure sulphuric acid of commerce is never really pure and as the same objection applies to the nitrate of ammonia a sediment will be found in the bottles at the end of a few days and the liquor will
4245 then be perfectly clear and colorless in such circumstances it
will be adviseable to decant the liquid into other bottles before laying by for use—I next prepare a saturated solution of hydrochlorate of ammonia which is to be filtered and then bottled for use the battery combination of which the liquids before named form part and which I find most economical and powerful—is arranged as follows—In a strong glass or well glazed porcelain or cemented wooden vessel three inches by two and a half internal measurement ~~and three~~ and a half deep is placed a piece of Mosselmans sheet zinc of the annexed form U the sides being nearly the height and width of the vessel and the narrow part or bottom one and a half inch wide within this upturned sheet of zinc and resting on it is a cell of seasoned sycamore or porous biscuit ware three fourths of an inch internal diameter and of the depth and breadth of the zinc which surrounds it—within this cell is suspended by a binding screw from a lacquered brass or gilt metal bar which crosses

the outer vessel and rests thereon—a piece of thin sheet platina cut so as to pass freely into the cell and of similar depth—the battery is now perfect and to put it in action the nitrate of ammonia acidulated solution is to be poured into the cell holding the platina to within half an inch of the top of the cell—the saturated solution of muriate of ammonia is to be poured into the glass vessel in contact with the zinc until it attains a level with the other solution, a binding screw with a copper shank is to be rivetted to the zinc as preferable to soldering and on closing the voltaic circle the battery is in immediate and powerful action and will preserve its original strength until the nitrate solution assumes a very light green color when it will be requisite to draw off by means of a syphon arrangement or syringe the exhausted liquor and replenish with fresh while it is in the act of passing off which can be done without any difficulty or loss of power by many simple contrivances which are well known the muriate solution may be removed similarly but will not require to be changed unless the battery is maintained in action more than twelve hours, what I here observe in regard to changing the solutions is only applicable to the simple and diminutive form of battery which I have been describing In batteries of a larger size the plates of which are five or six inches square and the containing vessels larger in proportion (which size be it observed is best adapted for the production of powerful electro magnetic effects) the nitrate liquor may be preserved in its original strength by a convenient apparatus attached to the battery which will gradually supply the inner and outer compartments with a given quantity of fresh fluids in a given time while the weak liquors are carried off into a reservoir connected with the battery for the purpose of obtaining therefrom by simple chemical operations various substances whose 4246 mercantile value will tend to reduce considerably the cost of the battery consumption in this combination there are various advantages which I do not believe to be attainable in any other battery known the use of a saturated solution of muriate of ammonia in contact with the zinc obviates the unwholesome troublesome and expensive process of amalgamation for there is no local action therefore the zinc lasts much longer in this combination than in any other again wooden cells or partitions which are the most durable diaphragms of any may be used with the prepared liquor the noxious fumes produced by the nitric acid battery are avoided the action is sustained without a fresh supply of fluids for a long period and the electric effects are so proportioned in regard to quantity and intensity that the electricity developed is peculiarly applicable to the production of great electro magnetic power it is to be particularly observed that although I have hitherto confined myself to the description of the effects of the combination of certain proportions of nitrate of ammonia water and sulphuric acid I do not restrict myself to the use of those particular proportions for I frequently use the salt of ammonia in various other proportions with water and sulphuric acid although I prefer the mixture described herein neither do I confine myself to the use of nitrate of ammonia alone for I use nitrate of potash and other nitrates in combination with sulphuric acid but prefer the nitrate of ammonia as most effective and most manageable in consequence of no precipitate being formed while the battery is in action neither do I restrict myself to the use of muriate of ammonia in connection with the zinc for I use occasionally muriate of soda and sulphate of zinc in saturated solutions but none of the muriates or sulphates aid in developing a current nearly so strong as the volatile alkaline salts hereinbefore described I would here remark that whenever the action is stopped it will be proper to remove the diaphragm cell and place it in water slightly acidulated and in any form of battery where the diaphragm is not moveable then to draw off the liquid contents and pour in acidulated water

The second part of my invention consists of the application of electricity—no matter by what combination it may be produced—to the attainment of continued light by the adoption of a mode of arrangement which enables that light to be maintained and regulated and applied to any purpose for which light may be required It is very well known that electric light (so called) of great intensity has been frequently produced by the instrumentality of powerful voltaic combinations but beyond establishing the fact—the light itself was of no use inasmuch as the arrangements by which it was developed were imperfect which prevented the light from being sustained the usual mode of exhibiting this electrical effect was by arming the electrodes of a powerful
4247 voltaic battery with charcoal points or one charcoal point
and a fine platina wire which points were brought into contact either in the atmosphere or in an air pump vacuum and then removed slightly apart when an arc or brush or starlike light was developed which however ceased or declined after a few seconds and was only renewed by bringing other parts of the electrodes into contact now my invention consists of the follow arrangements—A glass globe similar to that in present use for shewing electric light *in vacuo* is similarly furnished with two brass caps in opposite parts of the sphere through which communication may be made with the interior and by one of which the globe may be exhausted at pleasure we will suppose the caps to be in vertical line when the globe is fixed on its stand and the upper cap to *to* contain a glass or insulated metel tube which passes through the cap and reaches nearly to the centre of the interior of the sphere this tube is made to taper cone-like from within an inch of its internal extremity to the extremity itself so that the opening at that end shall not be more than an eighth of an inch in diameter through this tube a thick copper wire working in an air tight collar in the brass cap is made to pass until it reaches within a quarter of an inch of the conical end of the tube where it is united to a fine platinum wire which projects beyond the tube being wound into a spiral form externally the coiled part being one eighth of an inch in diameter and a quarter of an inch in length—The thickness of this wire (and this remark applies to the other proportions of the apparatus) must depend upon the power of the battery and quantity of light required for its object being to develope a white heat when acting as the positive electrode if too

thin it would be liable to melt if too thick it would not produce sufficient heat Opposed to this wire which forms one electrode of the battery is another thick copper wire passing through the opposite brass cap and also through an air tight collar having at its extremity within the globe a coil of thin platina wire similar to that already described and for a similar purpose and with this difference only that within this coil is a small piece of spongy platinum these electrodes can be made to touch or separate by means of screw arrangements in the caps—The glass or other tube already described is now to be filled with finely pulverized box-wood-charcoal or plumbago and on connection being established between the electrodes and the battery one of the fine platina coils becomes white hot the charcoal which falls through and around both coils is ignited and a light pure and intense is thus obtained which is kept up by the continually changing points of contact of the coils with the charcoal powder as by its gravity it descends slowly through the tube and falls to the 4248 bottom of the sphere thence to be withdrawn for future use for the better understanding of the arrangement just described I annex a sectional view of the apparatus A A represents the glass globe B the glass or metal tube with conical end holding pulverized charcoal, C C brass caps through which the electrodes and glass tube pass—through air-tight collars—D D copper electrodes to which the terminal platina coils are attached E E the thin platinum wires coiled F F bending screws to connect electrodes with battery It will be apparent that the apparatus described may be constructed in divers forms so as to fit it for the various illuminating purposes to which it may be applied the annexed form attached to an ornamental stand is applicable to the lighting of public or private apartments

The third part of my invention consists in certain improvements in the application of electricity to the obtainment of motion—The first improvement consists in a mode of constructing electro magnets by which from a given weight of iron more attractive power may be obtained than has been hitherto developed in any other known form of electro magnets thick copper or other wire covered with cotton or ribbon or from eight to ten very thin wires bound together and similarly covered are laid upon a strip of sheet iron previously softened say six inches in width three feet long and one eighth of an inch thick the wires are placed parallel to each other and to the sides of the sheet iron and separated by intervals of one eighth of an inch or more (or laid close together) and by an interval of half an inch in the centre of the strip before the wires are so laid one end of the strip of iron is to be rolled upon a cylindrical rod of iron or other substance of half an inch or an inch in diameter according to the size of the magnet required so as that upon the withdrawl of the rod one end of the sheet shall form a hollow cylinder the wires are then to be laid as before described upon the remaining length of the strip and that part of the iron which has been already turned up is to be rolled on thus enclosing the wires previously laid upon its surface and when rolled to the other end presenting a compact electro-magnet each wire having a surface of iron on both sides and

thus exercising a double magnetising effect when the electric current is sent through it an enormous surface in a given weight of iron is thus obtained and the course of the current being short upon this encreased surface it will be evident that in the construction of large electro magnetic engines immense power may be obtained in small space and much unnecessary weight and cost of iron got rid of it will be observed that the strip of iron when rolled up is hollow in its centre this hollow may be filled when desired with a solid rod of iron or a bundle of iron wires which will increase the
magnetic effects and the roll of iron itself may be covered on the
4249 outside with insulated wire like any common electro mag-
net—The annexed diagram represents the strip of iron before rolling—A A A A The strip of sheet iron laid flat—B B one end of the sheet rolled once so as to leave a hollow for the introduction of a rod of iron or a bundle of wires—C C the covered wires laid upon the sheet before rolling their ends being turned out at each end of the sheet for the purpose of connection with the battery or with each other—It is to be borne in mind that the iron strip may be of any degree of thickness that will admit of its being rolled that it may be of any length of any breadth—or that very thin strips may be laid one on the other and rolled up together and should the sheet iron beyond a certain thickness prove refractory in rolling and danger of injury to the intervening wires be apprehended this difficulty is easily obviated by placing a strip of lead or other soft metal upon the sheet iron in the first instance then rolling the iron upon the lead—then melting out the lead and finally coiling and packing the wires in the spaces occupied previously by that metal.

My second improvement is a modification of the first and is simply a combination of soft iron hollow cylinders of quarter inch or any thinner substance upon which covered wire is coiled singly from end to end and one cylinder so covered introduced into another a size larger—the larger covered in a similar manner and introduced into a third of greater diameter and so on until the combined cylinders attain the size required the whole are then bound together by a screw passing through their centres from side to side of the external cylinder

My third improvement consists in applying the above described electro magnets or any others to the production of motion in machinery by an improved mode of arrangement whereby greater force is obtained than by any of the methods in present use A series of electro magnets as above described or any others are passed through circular holes at regular distances all round the felloes or rim of a wooden wheel fixed in a metal or other frame and parallel to its axis—an equal portion of each magnet projects at either side of the rim of the wheel and fixed in frames on each side of the wheel and parallel to it are a number of electro magnets of equal size and strength corresponding with the number in the wheel and of equal stength The spokes of this driving wheel are of sufficient substance to admit of a certain number of straight electro magnets being passed through them also parallel to its axis and in the frame work on each side of this wheel are fixed electro-magnets radiating from a centre formed by the axis of the driving wheel which works in the frame and in their relative distances from each other corresponding with the magnets fixed in the driving wheel—The 4250 poles of the magnets in the frames are opposed to the poles of the magnets in the wheel during the revolution of which attraction is converted into repulsion by a change in the polarities of the fixed magnets effected by a commutator worked by the wheel I deem it proper to add that I prefer suspending or cutting off the electricity of the fixed magnets to changing their polarities but am prevented applying this method in my improved engine it being patented by another party—The fixed magnets are worked by one battery or series of batteries and the moving or wheel magnets by another and the connections with the batteries are effected by those modes which are generally known and adopted in electro magnetic motive arrangements

Having thus fully described and set forth the nature of my said improvements and the manner of carrying out the same I will now explain what I claim as my invention.

First I claim as my invention the developement of the electric principle by means of a combination consisting of a liquor composed of nitrate of ammonia or nitrate of potassa or other soluble nitrate water and sulphuric acid in the proportions hereinbefore described and also in other proportions (those however herein given being the best) in association with platina or other negative metal or precipitate of one metal upon another or other substance not metallic which may be substituted for the negative metal and which is capable of resisting the action of such compound fluid and further consisting of a saturated aquous solution of muriate of ammonia or muriate of soda or other soluble muriate or sulphate or nitrate in association with zinc or other positive metal the whole forming a voltaic circle or combination consisting of the acidulated nitrate solution platina saturated solution of muriate of ammonia and zinc with the addition of a wooden or other diaphragm and I not only claim this particular combination as my invention but I also claim specially as my invention the compound liquor of which nitrate of ammonia sulphuric acid and water *form* the ingredients in the proportions hereinbefore set forth (which I consider best) or in varying proportions—or of which a different soluble nitrate—a different acid—and water are the ingredients—inducing however when combined a similar play of chemical affinities during the development of electricity in a closed vol-aic circle.

Secondly I claim the application of electricity whether produced by my combination or by any other to the development of a sustained light by the mode hereinbefore set forth and explained that is to say by the use of pulverised charcoal or plumbago in connection with fine platina or other wire or spongy platinum or 4251 both and also the mode or mechanical means whereby the charcoal is brought into contact with the platinum or other metallic electrode.

Thirdly I claim as my invention the two modes of forming power-

ful electro magnets herein described and also the particular modes of arrangement of the said improved electro magnets or other forms of electro magnets in the electro magnetic engine herein described.

And I further claim as my invention the particular mode of construction of the motive apparatus hereinbefore set forth as intended to convey motive power to machinery and to display the greatly encreased force produced by the described arrangement of the electro magnets.

In witness whereof I the said Frederick De Moleyns have hereunto set my hand and seal this twenty first day of February in the year of our Lord one thousand eight hundred and forty two

FREDERICK (L. S.) DE MOLEYNS.

Neale, Extra.

And be it remembered that on the twenty first day of February in the year of our Lord 1842 the aforesaid Frederick De Moleyns came before our said lady the Queen in her chancery and acknowledged the specification aforesaid and all and every thing therein contained and specified in form above written and also the specification aforesaid was stamped according to the tenor of the statute made for that purpose

Inrolled the twenty first day of February in the year of our Lord one thousand eight hundred and forty two

London: Printed by Eyre and Spottiswoode, printers to the Queen's most excellent majesty. For her majesty's stationery office.

King's specification.

To all to whom these presents shall come I, Edward Augustin King, of Warwick street, in the county of Middlesex, gentleman, send greeting:

Whereas her present most excellent majesty Queen Victoria by her royal letters patent under the great seal of Great Britain bearing date at Westminster the fourth day of November in the ninth year of her reign did for herself her heirs and successors give and grant unto me the said Edward Augustin King my ex'ors adm'ors and assigns her especial licence full power sole privilege and authority that I the said Edward Augustin King my ex'ors adm'ors and assigns or such others as I the said Edward Augustin King my ex'ors adm'ors or assigns should at any time agree with and no others from time to time and at all times during the term of years therein expressed should and lawfully might make use exercise and vend within England Wales and the town of Berwick upon Tweed the islands of Jersey Guernsey Alderney Sark and Man and also within all her said majesty's colonies and plantations abroad the "Invention of improvements in obtaining light by electricity" communicated to me by a certain foreigner residing abroad in which said letters patent is contained a proviso that I the said Edward Augustin King shall cause a particular description of the nature of the said invention and in what manner the same is to be performed to be inrolled in her said majesty's high court of chancery within six calendar months next and immediately after the date of the said in part recited letters patent as in and by the same reference being thereunto had will more fully and at large appear.

Now know ye that in compliance with the said proviso I the said

Edward Augustin King do hereby declare that the nature of 4255 the said invention and the manner in which the same is to be performed are fully described and ascertained in and by the following description thereof reference being had to the drawings hereunto annexed and to the figures and letters marked thereon (that is to say)—

(Here follow diagrams marked pp. 4258 and 4259.)

The nature of the invention consists in the application of continuous metallic and carbon conductors intensely heated by the passage of a current of electricity to the purposes of illumination. The metal found to be the most advantageous to use for the purpose, is that which, while it requires a very high temperature for its fusion, has but a feeble affinity for oxygen, and offers a great resistance to the passage of an electrical current. Platinum though not so infusible as iridium, has but little affinity for oxygen and offers a great resistance to the passage of the current, and as it is abundant and easily worked into the requisite form, it appears to be preferable to any other metal. The platinum should be worked into those exceedingly thin sheets known as leaf platinum. This may be accomplished by the ordinary process of the gold beater, but a more accurate method is to place a piece of platinum foil between two thick plates of rolled copper and reduce the whole to a thin sheet by rolling, when on separating the *the* copper pieces the platinum leaf will be found of uniform thickness in every part. In this way it may be obtained so thin that on holding it before a printed page the letters can be distinguished through it. A strip is to be cut from one of these sheets of a width proportionate to the quantity of the current which with Grove's cells having the platinum plates three inches long and two inches wide, is about one-fourth of an inch and of a length proportionate to the intensity which of course varies with the number of cells. Great care must be taken to cut the platinum strips of an equal width throughout, and with a clean edge, as if this is not carefully attended to, the strip will be unequally heated and will be fused in one part before the other parts have obtained a sufficiently high temperature to produce a brilliant light. The platinum strip is now to be suspended between two forceps in an instrument made for the purpose one form of which is shown in section in the drawing hereunto annexed and marked N°. 1. A is a square brass bar fixed into the wooden stand C having a binding screw F attached to its lower end. The two arms E D are attached to sockets which slide on this bar so as to admit of their being placed at different distances from each other. They are both bent at right angles as seen in the figure and terminated by broad forceps tipped with platinum. These forceps are closed by the milled screws H I; the arm E has a rod N with a screw cut on it passing through it and by means of the two nuts B B working on this rod, the arm may be adjusted to 4256 any required height and the distance between the forceps thus regulated. The rod passes through the stand and is

attached to the binding screw G. The socket K is lined with ivory or some other non conducting substance, so as to prevent any metallic communication between the arm E, and the bar; S is the strip of platinum leaf which is first clamped in the upper forceps; the arm E is now adjusted to any required height, and the lower forceps are closed so as to clamp the lower end of the strip of platinum. It may now be included in the battery circuit by attaching one of the wires to the binding screw at F and the other to that at G. The current should be one of considerable intensity and the distance between the forceps should be sufficient to prevent the platinum being fused. The distance may be lessened by raising the arm E, and shortening the strip of platinum until it attains the highest temperature it will bear without fusing or the same object may be attained by increasing the intensity of the current. The glass shade R which serves to screen the platinum from currents of air, dust &c. may then be placed over the apparatus as seen in the drawing annexed. When carbon is used it becomes necessary on account of the affinity this substance has for oxygen at high temperature, to exclude from it air and moisture. To accomplish this in the most perfect manner it should be enclosed in a To*o*ricel-i*eu* vacuum. One form of the apparatus for this purpose is shown in section in the drawing annexed and marked No. 2, *a* is a glass tube similar to those used for barometers, except that it has its upper end enlarged into a cylindrical bulb, and a stout platinum wire sealed in at the top. A binding screw is fixed on the top of the wire, whose lower end screws in the iron piece, *d*, to this piece the forceps *f* are attached, and it is connected with a similar piece at *h* by the porcelain rod *i*. The forceps *g* are attached to *h*, and clamp the lower end of the carbon piece *c* which has its upper end held by those at *f*. *n* is a copper wire which is fixed into the piece at *h* and extends to the bottom of the tube, the tube is filled with mercury in the same manner as a barometer, the usual precautions being taken to expel the air; its length independent of the bulb, should be about thirty inches, so that when it is inserted in a cup of mercury, a vacuum will be formed in the bulb.—The instrument is included in the electrical circuit, by connecting one of the wires from the magnetic or voltaic battery with the binding screw fixed on the wire, *e* and the other with a wire which passes into the mercury in the cup at the bottom of the tube. The circuit is thus completed by the column of mercury, and when it is depressed in the tube by the formation of vapor of mercury, the connection is preserved by the copper wire *n*; that form of carbon found on the interior of coal gas retorts which have long been used, is well suited for this purpose, and may
4257 be worked into the form of either small pencils or thin plates by the aid of the saw and file. As carbon will bear a very high temperature without fusion or volatization it may be employed when a very intense light is required. When an intermitting light for the use of light-houses or for other purposes is required it may be obtained by breaking the circuit at intervals by clock work; to effect this, one of the wires from the magnetic or voltaic battery is connected with a spring which is made to press on the circumfer-

ence of a metallic wheel fixed on one of the arbors of the clock, having certain portions of its surface cut away so as to break and close the circuit at any required intervals. When the apparatus is suitably sealed it may be applied to submarine lighting, and also to the illumination of places where it is necessary to guard against the inflammation of highly combustible or explosive compounds, as in powder magazines mines &c. When a current is of sufficient intensity two or more lights may be made in the same circuit, care being taken to regulate the power by increasing or diminishing the number of armatures if a magneto-electric machine is the source of electricity or the number of cells if a voltaic battery be used, so that the united resistance of the strips of platinum or carbon shall be sufficient to prevent the passage of such a quantity of electricity as would destroy them.

Claim—What is claimed as the invention is the application of continuous metallic and carbon conductors intensely heated by the passage of a suitably regulated current of electricity to the purposes of illumination as hereinbefore mentioned.

In witness whereof I the said Edward Augustus King have hereunto set my hand and seal this second day of May in the year of our Lord one thousand eight hundred and forty-six.

EDWARD A. (L. S.) KING.

Dowdeswell.

And be it remembered that on the second day of May in the year of our Lord 1846 the aforesaid Edward Augustin King came before our said lady the Queen in her chancery and acknowledged the specification aforesaid and all and everything therein contained and specified in form above written. And also the specification aforesaid was stamped according to the tenor of the statute made for that purpose.

Enrolled the fourth day of May in the year of our Lord one thousand eight hundred and forty-six.

Electric Light.

Greener & Staite's specification.

To all to whom these presents shall come we, William Greener, of Birmingham, in the county of Warwick, gunmaker, and William Edwards Staite, of Peckham, in the county of Surrey, Esquire, send greeting:

Whereas her present most excellent majesty Queen Victoria by her royal letters patent under the great seal of Great Britain bearing date at Westminster the seventh day of February in the ninth year of her reign did for herself her heirs and successors give and grant unto us the said William Greener and William Edwards Staite our ex'ors adm'ors and assigns her special licence full power sole privilege and authority that we the said William Greener and William Edwards Staite our ex'ors adm'ors and assigns or such others as we the said William Greener and William Edwards Staite our ex'ors adm'ors or assigns should at any time agree with and no others from time to time and at all times during the term of years therein expressed should and lawfully might make use exercise and vend within England Wales and the town of Berwick upon Tweed our invention of "certain improvements in ignition and illumination" in which said letters patent is contained a proviso that we the said William Greener and William Edwards Staite or one of us shall cause a particular description of the nature of our said invention and in what manner the same is to be performed to be in- 4262 rolled in her said majesty's high court of chancery within six calendar months next and immediately after the date of the said in part recited letters patent as in and by the same reference being thereunto had will more fully and at large appear.

Now know ye that in compliance with the said proviso we the said William Greener and William Edwards Staite hereby declare

that the nature of our said invention and the manner in which the same is performed may be stated generally as consisting in effecting the illumination of public and private buildings, streets, squares, and other public places by means of solid prisms or cylinders of carbon, enclosed in air tight vessels of glass or some other transparent substance and ignited or rendered luminous by currents of voltaic or magnetic electricity, such carbon being previously freed from the impurities with which it is ordinarily combined and divided on the surface thereof into numerous acute points or by means of rods or strips of platinum or some other like difficultly fusible metal enclosed in transparent air tight vessels and ignited or rendered luminous by currents of voltaic or magnetic electricity as aforesaid such metal being also divided on the surface thereof into numerous acute points or by means of hollow cylinders of carbon with surfaces either plain or acuminated, partially inserted within and placed in perfect contact with hollow cones of platinum, either plain or acuminated, the whole being enclosed in transparent air tight vessels as aforesaid, and the carbon being ignited or rendered luminous by voltaic or magnetic electricity also as aforesaid—or by a combination or combinations of the whole of the said means or methods or of any two thereof or of any of the parts thereof respectively—Both carbon and platinum have been before employed as media for the developement and exhibition of electric light, but carbon even in the purest states in which it has hitherto been obtainable, when ignited, or rendered luminous in an air tight glass vessel by means of electric currents has been found to give out various extraneous matters which interfere with the continuity of the light and which being precipitated on the inside of the glass vessel obscure and darken the same; and plain surfaced platinum when substituted for the carbon in the air tight vessel has never yielded more than a comparatively very feeble light. Now to obtain for the purpose of our invention a carbon absolutely pure or at least more nearly approaching absolute purity than any heretofore known, we proceed as follows—We take a quantity of what is known in commerce under the denomination of lamp black or of charcoal reduced to a state of powder, or of coke also reduced to powder which has been purified by the application of electricity from sulphur and other metallic mixtures according to the process for which Jabez Church of Colchester
4263 has obtained letters patent of date the twentieth of December one thousand eight hundred and forty five; and digest the same in dilute nitro muriatic or other acid—We then strain the lamp black, or charcoal, or coke, from the acid and wash it several times with water and we next wash it in some weak alkaline solution or carbonated alkaline solution and finally we wash it with distilled water until no traces of impurity are perceptible The carbon thus highly purified we next bring into a state of great dryness and then convert it into solid prisms, or into cylinders both solid and hollow by means of a hydraulic or screw or fly press (in the same way as the well known porcelain buttons are formed) and sometimes the better to ensure perfect dryness and homogeneous-

ness we expose the said prisms or cylinders to intense heat in a furnace for about twenty four hours—To give the solid carbon prisms or cylinders the numerous acute points on their surfaces before mentioned they are cast in suitably indented dies, or the points are afterwards cut out in them by means of a fine saw—By opposing two such acuminated surfaces the one to the other, we secure this advantage, that should the electric currents cease between any two points (as happens frequently in the ordinary mode of igniting carbon by electricity when there are only two points in opposition) the currents will be kept up by the remaining points and the light be so maintained without any material interruption or abatement—The same purpose may in some cases be effected by substituting for bodies with such acuminated surfaces a multitude of thin strips of charcoal separated from each other by platinum foil, and bound together by platinum wire—Instead also of employing either lamp black or charcoal or coke we sometimes substitute plumbago, or black lead, prepared formed and used in the same way; but the sort of carbon we prfer before all others is that prepared in the manner before mentioned from coke by Church's patent process—When we use platinum or any other difficultly fusible metal as the illuminating medium we multiply as much as we conveniently can the number of separate points on its surface, and with this view we either perforate a solid sheet of the metal with a multitude of minute holes or we take it in the form of wire and weave it into a gauze of sufficient thickness to resist the heat produced by the electric current without fusing—When we employ the combination before mentioned of hollow cylinders of carbon with hollow cones of platinum, we arrange them as follows—Supposing a voltaic battery of any of the most approved forms to be employed, we connect each of the two conducting wires namely the positive and negative with a hollow cone of platinum either plain or acuminated and place the cones with their bases facing, but at a little distance from one another—we then connect the two cones by placing between them
4264 a hollow cylinder of carbon either plain or acuminated, and
insert it so far into the cones at the two ends as to be in perfect contact therewith all round—The relative diameters should be such as to render it necessary to introduce the cylinder but a small way into the cones—Such cones and cylinders may be used either in single sets or in any number of sets which the battery or batteries employed may be adequate to supply—The sets too, may be arranged in any order and they may be of any variety or varieties of size best calculated to produce an equable well sustained and brilliant light—When the platinum or carbon or other difficultly fusible metal (in whatever form employed) is placed within the air tight vessel of glass or other transparent substance, it may be either kept stationary or made to rotate on its axis—We think it unnecessary to describe either how the air tight vessel which is to enclose the illuminating bodies should be mounted or how the electric currents are to be conveyed to them from the voltaic battery or magnetic machine employed because there are many well known modes of doing so and we do not claim to have invented anything new in

these respects—We desire it farther to be understood that we lay no claim to the employment of carbon or platinum or other like difficultly fusible metal enclosed within air tight vessels as a medium for the developement and exhibition of electric light the suitableness of both bodies for the purpose when so enclosed (subject to the exceptions aforesaid) being long well known—But we declare that what we do claim as of our invention is—

First the employment as a medium for the developement and exhibition of electric light of carbon purified and prepared as before described.

Second, the employment for the said purpose of carbon and platinum or any other like difficultly fusible metal in solid prisms or cylinders divided on the surfaces thereof into numerous acute points, or in such other forms as to present numerous acute points as before described And

Third the employment for the said purpose of hollow cylinders of carbon either plain or acuminated in combination with hollow cones of platinum or other like difficultly fusible metal either plain or acuminated as before described.

In witness whereof we the said William Greener and William Edwards Staite have hereunto set our hands and seals this fifth day of August in the year of our Lord one thousand eight hundred and forty six.

WILLIAM (L. S.) GREENER.
W. E. (L. S.) STAITE.

4265 And be it remembered that on the fifth day of August in the year of our Lord 1846 the aforesaid William Greener and William Edwards Staite came before our said lady the Queen in her chancery and acknowledged the specification aforesaid and all and every thing therein contained and specified in form above written And also the specification aforesaid was stamped according to the tenor of the statute made for that purpose.

Duckworth.

Enrolled the seventh day of August in the year of our Lord one thousand eight hundred and forty six.

A. D. 1850. No. 13302.

Electro-magnetic Apparatus for Obtaining Motive Power, Light, and Heat.

Shepard's specification.

To all to whom these presents shall come I, Edward Clarence Shepard, of Parliament street, in the city of Westminster and county of Middlesex, gentleman, send greeting:

Whereas her present most excellent majesty Queen Victoria by her royal letters patent under the great seal of the United Kingdom of Great Britain and Ireland bearing date at Westminster the twenty-fourth day of October one thousand eight hundred and fifty in the fourteenth year of her reign did for herself her heirs and successors give and grant unto me the said Edward Clarence Shepard my ex'ors adm'ors and assigns her especial license full power sole privilege and authority that I the said Edward Clarence Shepard my ex'ors adm'ors and assigns or such others as I the said Edward Clarence Shepard my ex'ors adm'ors or assigns should at any time agree with and no others from time to time and at all times during the term of years therein expressed should and lawfully might make use exercise and vend within England Wales and the town of Berwick-upon-Tweed and in the islands of Guernsey Jersey Alderney Sark and Man and in all her said majesty's colonies and plantations abroad my invention of "certain improvements in electro-magnetic apparatus suitable for the production of motive power of heat and light" communicated to me by one Floris Nollet of Brussels in which said letters patent is contained a proviso that I the said Edward Clarence Shepard shall cause a particular description of the nature of my said invention and in what manner the same is to be performed by an instrument in writing under my hand and 4268 seal to be enrolled in her said majesty's high court of chancery within six calendar months next and immediately after the date of the said in part recited letters patent as in and by the same reference being thereunto had will more fully and at large appear.

Now know ye that in compliance with the said proviso I the said Edward Clarence Shepard hereby declare that the nature of the said invention and in what manner the same is performed according as the same have been communicated to me by the said Floris Nollet are fully set forth and ascertained in and by the present specification thereof reference being had to the drawings hereunto annexed that is to say the said invention may be described generally as consisting

Firstly of certain improvements in the means and apparatuses used for developing electricity and applying that physical agent to various useful purposes.

And secondly in certain improvements in magneto-electric apparatuses or arrangements having for their object the production of different physical and chemical phenomena and more especially the disengagement of certain gaseous elements which by their elasticity their dilatation and their combination produce either motive power or light or heat.

I.—*Description of the Improved Apparatuses.*

Figure 1 A B and A^1 B^1 are parts of four compound magnets each composed of from 7 to 9 bars of very hard tempered cast steel not less than eighty-four centimetres (33 inches) in length 5 centimetres (2 inches) in breadth eight centimetres (three and one eighth inches) in thickness magnetised by means of electro-magnetism. Each bar is bent into two parallel legs about four to five centimetres (one & five eighths of an inch to two inches) apart. These four magnets are arranged in two pairs by means of plates of wood or brass and brass adjusting screws *c c* the magnets being kept at the same distance apart as the bars of which each magnet is composed. The two pairs of magnets are fixed horizontally on the base of the frame of the apparatus so that their opposite poles A B A^1 B^1 face one another and at such a distance that the ends of four helices pass during their rotation immediately over and between the poles of these magnets and as near to them as may be without touching. The positions of the magnets A^1 & B^1 are indicated by dotted lines C C. C^1 C^1 are the four helices forming part of a set of eight connected by the armatures D D and D^1 D^1 figure 2 which cross one another being furnished with an insulating substance interposed between them at the point of intersection. The helices
4269 are united in pairs by being mounted upon a wooden spindle
the whole are joined together by the armatures D D and the axle *a*. These helices are formed of two wires of very fine copper about one millimetre (one thirty-second of an inch) in diameter covered with some insulated substance as silk cotton varnish or what is still better a thin layer of gutta percha, through which the wire has been drawn while both wire and gutta percha are at a temperature nearly that of boiling water (one hundred degrees centigrade). These two wires are wound in the ordinary manner round a hollow soft iron axis about five to six centimetres long

(two to two & three eighths inches) and about four centimeters (one & five eighths inches) in diameter. The length of each of these wires should at least be about one hundred and fifty metres (one hundred and seventy yards). The hollow cylindrical centres or axes of the helices terminate in two plates of about three centimetres (one and a quarter inch) in width bent back against the discs or ends of the helices and the extremities of the plates are bent up at right angles to a height of from five to six millimetres (three sixteenths of an inch) and kept sufficiently apart to allow of the poles of the magnets passing freely without touching during their rotation. The horizontal axis *a* is centred on two steel pivots and passes through the middle of the armatures where it is firmly secured to them. This axis carries two pairs of ivory discs E E E¹ E¹ into which are inserted four segments of copper cemented by means of gutta percha and separated by slips of ivory of about one millimetre (one thirty-second of an inch) in thickness which last are kept a little in relief to prevent the copper segments from ever touching two of these slips at once. Figure 3 is a side view of one of these discs. The metallic segments communicate by means of arms arranged in the form of a cross the direction of the diagonal of one disc corresponding to the diagonal of the other of the same pair whereby all the currents are made to flow in one direction. F is a pulley about three centimetres (one and a half inches) in diameter over which is carried a gutta percha band which passes over a second pulley of about 1.5 metres (fifty-seven inches) in diameter placed immediately above the other which arrangement allows of a rotary speed of from fifty to one hundred revolutions per minute being obtained with at the utmost not more than half a man's power. By these means two pairs of primitive currents constant in one direction and of an intensity capable of producing various physical phenomena such as of heating to redness and melting metallic wires and rendering large cones of carbon incandescent causing rapid chemical decompositions, &c., but instead of making them thus act on the poles of the wires which terminate this arrangement of primitive current helices they are made to communicate and pass into one or other of two supplementary
4270 systems herein-after described namely the system of spirals or the system of current condensers. In figure 4 G and G¹ represent two arrangements of spirals composed of a hollow central cylindrical axis made of magnetized metal from eight to ten centimetres (three and a half to four inches) in diameter about twelve centimetres (four and three quarters inches) in length and terminating in two discs of dry varnished wood. To form the spirals two series of round or flat copper insulated wires of as nearly equal diameter as may be to that of the electro-multiplying helices and exactly of the same length as the distance between the two discs are arranged on a horizontal plane like the warp of a web. The wires thus arranged are wound on the central axis and parallel with it so as to form a cylinder of about fifteen centimetres (six inches) in diameter one of these cylinders communicates by the central end of the first spiral with the wire of the positive pole of two pairs of

primitive currents. The other end of that spiral is soldered to the central extremity of the third spiral so that the second spiral has its two ends free. The upper end of the third spiral is in its turn soldered to the central end of the fifth spiral leaving the fourth free and so on throughout the series the same arrangement being adopted for the second pair of currents. It results from this arrangement that all the spirals of odd numbers are soldered together and form one immense helix traversed by the primitive current whilst each of the spirals of even numbers is individually traversed by a current of induction. The same phenomenon takes place in the second cylinder but here the currents are reversed because the large helix likewise formed of the odd spirals communicates with the negative pole of the first pair of primitive currents. By soldering the centre or inner end of an odd spiral of the first cylinder with the end of the circumference of the corresponding spiral of the second cylinder the two free ends of these spirals form the two poles of a powerful induced or secondary current capable of producing the same phenomena as the primitive current. It has been proved by experiment that a wire traversed by an electrical current will produce a current of induction or secondary current in an adjacent wire bent back in any given direction as long as it is parallel to and does not cross the direction of the wire of the primitive current but in all helices with double wires hitherto contrived the induced or secondary currents do not perfectly realize these two essential conditions because the wires are forced to cross each other and to return in an opposite direction to the other extremity of the helix. Now in my arrangement of spirals on the contrary the direction of the wires remains constant from one end to the other and each spiral of the induced or secondary current is enclosed throughout
its whole length between two spirals traversed in the
4271 same direction by the primitive current whence it necessarily
follows that the two currents must act concurrently so that
each shall have a tendency to increase the power of the other. If this primitive current did not exist and the two spirals placed one to the right and the other to the left were traversed by currents in the same direction as they are in the case supposed it is evident that they would produce in the spiral interposed between them an induced current in the same direction as that of the actual primitive current. It appears farther from recent experiments that the electric current traverses a copper wire such as I employ with a speed of at least one hundred thousand leagues per second so that if the wire were of that length and an intermittent current were passed through it each second it would be continuous in the wire because it would always enter by one end of the wire just as it passed off by the other but if instead of one vibration or one induction per second it were possible to produce one hundred or more in the same time it is evident that a current of proportionately increased intensity would be produced. In place of the wires flat spirals of thin metal two or three times broader than the wires may be substituted with advantage.

II.—*Oscillating System.*

Another arrangement of the system of helices which I have found to succeed well consists in fixing the whole of the eight helices at the end of a pendulum of about one metre (thirty-nine inches) in length mounted in a frame as represented in figure 5 having a vertical oscillatory movement between the poles of the magnets which are arranged horizontally a similar arrangement being adopted at the other end of the lever. Eight pairs of helices h h h^1 h^1 may be then set to work at the same time and this number may be doubled trebled or even increased at pleasure within a certain limit by prolonging the arms of the lever to a sufficient extent for which purpose the levers may if necessary be composed of several parts articulated or jointed together. The movement of the pendulum is communicated and the range of the oscillations regulated by means of an excentric L the lower end of the rod M of which is jointed to one of the arms B of the pendulum or lever N at a convenient distance from the fulcrum O. This excentric is fixed on a shaft placed perpendicularly over the lever and put in motion by two pulleys P P^1 and band R the small pulley P is placed on the shaft of the excentric and the large pulley P^1 is about twenty or twenty-five times the diameter of the smaller one—is put in motion by means of a handle S.

III.—*Rolling System.*

In this system (see figure 6 and figure 7) the magnetic bars
4272 are kept in their horizontal position but the helices (h h h^1 h^1)
are carried on a little carriage C which runs on rails R R and passes alternately in front of the poles of the magnets by means of a to and fro movement derived from two excentrics keyed on one common axis side by side but diametrically opposed in their excentricities in order that there may be an equilibrium of action on both sides of that axis each excentric moving the same number of pairs of helics. For the eccentrics cam wheels may be substituted or any other equivalent mechanical means. By this sort of movement little force is expended and at the same time there is little risk of derangement of the parts. The different parts of the rails R R are insulated from each other by ivory plates B B. C is one of the carriages by which the helices are made to travel in front of the magnets. Any desired number of these little magneto-electric waggons may be placed on the same rails and may be put in motion by the same mechanism. The ivory plates B B serve to break the flow of the currents and the cross bars X X unite them again so that they may all flow in one direction.

IV.—*The Actions and Re-actions of Soft Iron on the Helices with Primitive Currents and on those with Induced Crrents.*

Experiments which have been made proved that the actions of currents for developing magnetism in soft iron and the re-action of this same soft iron transformed into a temporary magnet are not reciprocal in the different relative positions which may be given to them. For example it is known that if soft iron is enveloped in a helix of wire or metallic ribbon covered with some insulating substance and brought near to the pole of a soft iron magnet there is an electric current induced in the wire and if reciprocally an electric current is made to pass through the helicoidal wire, magnetism is developed in the soft iron without the presence of any magnet, but if the metallic wire helix is placed in the hollow soft iron cylinder and the soft iron is subjected to the action of the poles of a magnet even of a very powerful one no current is developed in the helix. But it is not the same thing as to the action and re-action of two insulated helices mounted end to end upon one hollow axis. In this case if the primitive current is made to pass into the upper helix a current of contrary direction is produced by induction in the lower helix while at the same time the soft iron centre is magnetized which in its turn re-acts on the lower helix in a manner corresponding with the action of the upper helix. There is thus obtained in the lower helix a very powerful current by double induction and the primitive current far from being weakened is increased by the re-action of the electro-magnet so that it can 4273 be made to pass into a numerous series of double helices (arranged as aforesaid) before closing the circuit of the primitive current. And these different induced currents may evidently produce phenomena like those which the primitive current itself produces.

V.—*Current Condensers.*

When the positive polar wire of the primitive current is brought into communication with a thin leaf of metal or even with leaves of paper thinly coated with metal such as copper silver or gold leaf or with varnish and also against another similar sheet communicating with the negative polar wire the current is condensed on these leaves and by separating them quickly and repeatedly a very remarkable increase in the intensity of the current is produced accordingly it has been found that the prolongation of the conducting wires soldered to the end of these leaves yields to a decomposing instrument (rheometer) a quantity of gas greater than when the polar wires of this current pass directly to the rheometric apparatus. The idea therefore suggested itself that if there were placed in the middle of this condenser another similar condenser charged with a considerable quantity of electrity that condenser would transmit its electricity to a second condenser of the same sort or to the pole of induced or secondary currents as before-mentioned and thereby greatly increase their intensity. These condensers acquire a still greater power when constructed of very thin metallic bars varnished and wound round a roller or hollow cylinder made of well annealed thin sheet iron. From these arrangements I obtain a series of very powerful induced or secondary magnets. The success attending the preceding arrangements led to the trial of an experiment to make the primitive current pass through dry piles (piles sêches) and through secondary piles (piles secondaires) and the result has shown that a considerable increase may be thus effected both in the primitive current and in the induced or secondary currents. So also it seemed that a very advantageous improvement might be made in the apparatus for decomposing water acids salts &c. by charging the portions of any liquid desired to be composed with fluid of a corresponding character. For example if the portion of the liquid (say water) required to be decomposed in which the positive pole has been plunged and at which pole the oxygen should be given off were already positively electrified then it should seem to follow that on the discharge of the positive currents taking place the action of the positive fluid with which that portion of the water is already saturated would unite with the action of the polar fluid to attend the oxygen and repel the hydrogen and a like arrangement being applied to the negative wire it ought also to produce an analogous action. If so then that concurrence of actions ought to increase 4274 the decomposition of the liquid and consequently the production of gas. And this is in fact what is accomplished by the arrangement of decomposing apparatus next to be described. I bend a glass tube into two branches A A as represented in figure 8 which I contract or narrow at the bend B. I insert into each branch a tube of copper C C and connect it closely to the glass by a resinous luting. To the lower end of this tube which is open there are soldered from ten to fifteen ends *a a a* of fine platina wire ~~placed at~~ equal distances from one another and disposed in the form of a circle. These wires are immersed about one centimetre (three eighths of an inch) in the liquid to be decomposed which is contained in the glass tube. The copper tube C C should be carefully varnished on the inside especially in all that part which is inserted into the glass tube. The copper tubes are closed at top by well luted stoppers D. D made of varnished cork through which two tubes are passed one of which E is of glass and immersed in the liquid to be decomposed outside the glass tube E is connected to or prolonged by a tube made of gutta percha or India rubber or of glass or metal varnished on the inside and of about one metre (thirty-nine inches) long. The outer surface of this last tube is coated with metal that may act partially as a polar conductor and communicate with the copper tube from which the platina wires are dependent. Both branches of the tube are alike in their construction. By these means the liquid contained in the outer tube is electrified by induction and consequently charged with fluid of the same character as that of the polar wire which acts upon it. The liquid of one side passes to the polar tube of the other and reciprocally. It may here be observed that in order to preserve the flexibility of the gutta percha or India rubber tubes without impa-ring their quality as conductors either inside or outside they are covered with a thin continuous metallic surface by means of electrotyping and if necessary the surfaces are also varnished over with a solution of lac added to gutta percha. When decomposition is required to take place in a great number of vessels at the same time it will be found advantageous to employ a long prismatic porcelain trough divided by cross partitions into compartments communicating with one another two by two in order to separate the gases as in the case of the tube with two branches. This trough should be provided with a rather larger edge or flange to which an overlapping cover should be carefully luted and further fixed by means of a metallic frame with adjusting screws. There should be two circular openings in the cover above each of the two cells of the same compartment as shewn in figure 9 and the openings should be luted where the tubes are inserted as represented at figure 8.

4275 When great quantities of hydrogen gas are desired to be obtained it is advantageous to employ hydrochloric acid, and in this case the chlorine which would be disengaged like oxygen at the negative pole might be utilized for the manufacture of chlorides. If the hydrogen gas is intended for lighting I make it pass in a very divided state through camphine or other combination of alc*h*ohol or ether with an essential oil or other suitable hydrocarburet in order to render the flame more white and more intense.

VI.—*Apparatus for Lighting in a Vacuum.*

When it is desired to light by means of the incandescence of charcoal I employ an arrangement of apparatus similar to that which is represented in figure 10. A is a globe of glass which may if desired be ground or obscured on the inside in order to disperse and soften the intensity of the light. The stopper B of this globe is very carefully luted, and two insulated polar wires P and N of about two millimetres in diameter are passed through it. One of these wires is soldered to the side and towards the upper end of a copper tube C of about 1 decimetre (4 inches) in length. This tube is intended to hold a little cylinder of charcoal which is kept constantly pushed down from above by a small cylinder of lead which is of a weight adjusted to the purpose. The other polar wire comes out under the lower end of this tube at about one centimetre (three eighths of an inch) distance from its extremity and terminates in a little cone D of prepared charcoal or coke and against the top of which the little charcoal cylinder E rests which when the current is established becomes incandescent and remains in that state a very long time because the small portions which are consumed are continually replaced by a portion of the cylinder which the metal presser forces onto the top of the cone. A tube of glass or other suitable substance also passes through the stopper and admits of its being connected to the pneumatic receiver in order to create a vacuum in the globe. The tube is afterwards cut and hermetically sealed in order to prevent the re-entry of air.

VII.—*Prime Motive Power.*

The motive power engine most proper for the purpose of this invention is one of the form of an atmospheric steam engine without the boiler feeding pumps and condenser. The dimensions of this motive power engine ought to be proportionate to the force desired to be obtained but the bottom of the cylinder (see figure 11) 4276 should be provided with a valve V opening from the inside to the outside whereby any slight excess of steam will pass away with the water of condensation and produce the effect of reaction at the moment of the combination of the oxygen and hydrogen gases in order to reconstitute the water in the state of steam. This valve is held up by a helical spring *h*. Just above the bottom of the cylinder is a small tube T with a neck to which is screwed a stuffing box S in which is placed an insulating ring through which passes a rod R which forms the axis of a small toothed brass wheel W. The upper side of this box is perforated with an opening also provided with a boss *r* of some insulating material in which a metallic wire P is luted which communicates with one of the polar wires of one of the pairs of helices of the electro-magnetic apparatus the other polar wire N being attached to the end of the prolongation of the axis of the wheel a little beyond its bearing G. This prolongation carries a pully L to which motion is imparted by means of a strap from another pulley of a greater radius and which is not shewn in the drawing. There is fixed on the same axis R a little toothed wheel *w* which gears into another wheel fixed on the axis of the fly wheel of the machine and which is provided with teeth only on a very small portion of its circumference so that in one entire revolution of the fly wheel it may transmit its motion only during an exceedingly short interval to the wheel W and just at the instant at which the piston has made about one-fourth of its stroke. Numerous electrical sparks are thus thrown out every time that the teeth of the little wheel W enclosed in the box slide over the flattened end of the conducting wire P communicating as aforesaid with one of the polar wires these sparks then ignite the gaseous mixture arising from the decomposition of water and admitted into the cylinder through a distributing apparatus (slide box). The quantity of gas admitted into the cylinder should be equal to about one fourth of its capacity experiments having shewn that under the pressure of the atmosphere the ignition of gases generated by the decomposition of water causes them to dilate during explosion to four times their bulk. The piston will then be forcibly driven to the end of its stroke when immediately the water resulting from the combination of the gases will become condensed on the cold sides of the cylinder and a vacuum is formed beneath the piston then the atmospheric pressure acting with its entire force on the upper side of the piston will cause it to descend rapidly and these motions continued will produce the rotation of the engine. Thus by keeping up the supply of gases and successively exploding them a continuous movement of the machinery connected with the piston may be obtained.

4277 VIII.—*Apparatus for Covering the Wires and Making the Helices or Spirals.*

In all electro-magnetic apparatuses the most delicate of the operations and that which involves the greatest expense is the manufacture of the helices and the spirals. An apparatus very suitable for these purposes is represented in figure 12. I generally prefer using very fine cotton of ten or twelve strands which will perfectly cover the metallic wires without much increasing their diameter. Four small bobbins of cotton may be arranged on one circle and then cotton of only three or four strands is employed but it should always

be as fine as possible. The apparatus above referred to will allow of a metallic wire being covered of whatever length without being necessary to cut it. *a* is a bench frame one end of which is provided with a spring-vice *b* for guiding the metallic wire and giving it the necessary tension. The wire passes through the hollow axis of a little pulley *c* which is furnished with from one to four arms perpendicular to the axis at the end of which there is affixed at right angles a small steel rod *d* threaded at its free end, on these rods are mounted the bobbins filled with cotton. A screw nut pushes before it on each rod a little spiral spring which presses a friction float against the bobbin in order to prevent it from turning too loose on its spindle and thus exercises a slight tension on the thread of cotton. The end of the cotton is fastened with a little insulating varnish after passing it through a small glass ring (which serves as a guide). Upon the metallic wire a cord or band passes from the small pulley *c* (which is at the utmost one and a half centimetres (five eighths of an inch) in diameter) into one of the numerous grooves of a long wooden cylinder *e* of about three centimetres (one and a quarter inch) diameter. This cylinder with numerous and equi-distant grooves has motion given to it by means of a band from another pulley *f* (of about one metre (thirty-nine inches) in diameter, so as to impart a very great quickness of rotation to the bobbins which supply the cotton for covering the metallic wires *g* thus great quantity of metallic wires may be covered at the same time in fact as many as there may be sets of cotton covering bobbins. On the axis of the large pulley *f* there is a fusee *h* provided with an endless chain or band which imparts motion to a cylinder *j* the diameter of which is about four inches which is also the size of the diameter of the top of the fusee so that the band at this point causes the cylinder to make one revolution at every turn of the large pulley. The steel axis *k* of this cylinder is about two centimetres (three quarters of an inch) in diameter and is prolonged over a support whence it passes
into two metallic sockets which allow of its making a to and
4278 fro movement. This movement is determined and regulated
by two long screw threads in relief on the main shaft one of which is threaded from right to left and the other in the reverse direction. Two half nuts each fixed on one of the ends of the arms of the levers *l l* gear alternately into the right and left hand threads and push the shaft backwards or forwards. A rod *s* attached to the spindle *k* alternately pushes the weighted lever l^1 from one side to the other and effects the change of the gearing of the nuts so that without the aid of the workman's hand the shaft would always go forwards or backwards the same distance moreover the two screws correspond in size to that of the diameter of the metallic wire which it is desired to roll upon the soft iron armatures *i*. Several like armatures may be placed on the prolongation of the axis corresponding to the number of metallic wires intended to be rolled up. Thus the rolling of the cotton on the metallic wires and the completion of the helices are effected at the same time and with the greatest regularity.

And having now described the nature of the said invention and the manner in which the same is performed I declare that the improvements which I claim as constituting my said invention are as follows

First I claim the arrangement of four compound magnets in the manner represented in figure 1 and before described.

Second I claim the combination of four pairs of helices with armatures and other appliances in the manner represented in figures 1 & 2 and before described.

Third I claim the system of parallel multiplying spirals united in cylinders of indeterminate length and producing powerful and active induced currents by their combination as before described.

Fourth I claim the oscillating arrangement represented in figure 5 and before described.

Fifth I claim the rolling arrangement represented at figures 6 and 7 and before described.

Sixth I claim the flat helices employed as substitutes for the wires in the system of flat spirals represented in figure 4 and before described.

Seventh I claim the magneto-electric current condensers as before described.

Eighth I claim the application of dry piles and of secondary piles for the purpose of increasing the intensity both of the direct and of the induced currents.

Ninth I claim the electro-chemical motive power represented in figure 11 and before described but only in so far as regards the cylinder and its appendages.

4279 Tenth I claim the apparatus for lighting by the incandescence of prepared charcoal before described.

And eleventh I claim the lighting by hydrogen gas saturated with vapour of any hydrocarburet and burning in ordinary gas burners as before described.

In witness whereof I the said Edward Clarence Shepard have hereunto set my hand and seal this twenty-fourth day of April in the year of our Lord one thousand eight hundred and fifty-one.

E. CLARENCE (L. S.) SHEPARD.

And be it remembered that on the twenty-fourth day of April in the year of our Lord 1851 the aforesaid Edward Clarence Shepard came before our said lady the Queen in her chancery and acknowledged the specification aforesaid and all and every thing therein contained and specified in form above written.

Jefferson.

And also the specification aforesaid was stamped according to the tenor of the statute made for that purpose.

Enrolled the twenty-fourth day of April in the year of our Lord one thousand eight hundred and fifty-one.

London: Printed by Darling and Son. For her majesty's stationery office.

4284 DEF'T'S EXHIBIT SLATER & WATSON ENGLISH PATENT NO. 212 OF 1852. M'ch 13, 1889. W. T. F., N. P. & S. E.

A. D. 1852. No. 212.

Applying Electricity to Illuminating Purposes.

Letters patent to Thomas Slater, of Somers place, New road, Saint Pancras, in the county of Middlesex, optician, and Joseph John William Watson, of Old Kent road, in the county of Surrey, doctor of philosophy, for the invention of "improvements in the application of electricity to illuminating purposes."

Dated the 4th October, 1852.

Provisional specification left by the said Thomas Slater and Joseph John William Watson at the office of the commissioners of patents with their petition on the 4th October, 1852.

We, Thomas Slater, of Somers place, New road, Saint Pancras, in the county of Middlesex, optician, and Joseph John William Watson, of Old Kent road, in the county of Surrey, doctor of philosophy, do hereby declare the nature of the said invention for "improvements in the application of electricity to illuminating purposes" to be as follows:

Our improvements consist—

Firstly. In adjusting the distances between the parts of the electrodes by means of an induced magnet or magnets or by means of an electric current inducing magnetism in helices of wire.

4285 Secondly. The use of a chemically compounded electrode containing caustic substances and the introduction of a certain amount of non-conducting material to check the excess of convection or otherwise alter the mode in which the same is performed.

Thirdly. The use of a governor or governors for regulating the supply of electricity to the illuminating apparatus and thereby increasing or diminishing the intensity of the light.

Fourthly. The use of several electrodes in the same lamp.

Fifthly. The making the support or supports of the electrodes the armature of an induced magnet or magnets.

Specification in pursuance of the conditions of the letters patent filed by the said Thomas Slater and Joseph John William Watson in the Great Seal Patent Office on the 4th April, 1853.

To all to whom these presents shall come we, Thomas Slater, of Somers place, New road, Saint Pancras, in the county of Middlesex, optician, and Joseph John William Watson, of Old Kent road, in the county of Surrey, doctor of philosophy, send greeting:

Whereas her most excellent majesty, Queen Victoria, by her letters patent bearing date the fourth day of October, in the year of

our Lord one thousand eight hundred and fifty-two, in the sixteenth year of her reign, did, for herself, her heirs and successors, give and grant unto us, the said Thomas Slater and Joseph John William Watson, her special license
4286 that we, the said Thomas Slater and Joseph John William Watson, our executors, administrators, and assigns, or such other as we, the said Thomas Slater and Joseph John William Watson, our executors, administrators, and assigns, should at any time agree with, and no others, from time to time and at all times thereafter during the term therein expressed, should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel islands, and Isle of Man an invention for "improvements in the application of electricity to illuminating purposes," upon the condition (amongst others) that we, the said Thomas Slater and Joseph John William Watson, by an instrument in writing, under our hands and seals or under the hand and seal of one of us, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent:

Now, know ye that we, the said Thomas Slater and Joseph John William Watson, do hereby declare the nature of our said invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement, reference being had to the accompanying drawings and to the letters and figures marked thereon—that is to say:

4287 Our invention- in improvements in the application of electricity to illuminating purposes consist—

First. In improvements in apparatus for employing electricity as an illuminating agent.

Second. In apparatus for governing electric currents so as to indicate the quantity and intensity of electricity and to increase or dimish the same when passing into any description of electrical illuminating apparatus.

Third. In a new mode of applying electric currents so as to cause an equable consumption of the electrodes.

Fourth. The nature and manufacture of the electrodes.

Fifth. The application of electricity to the purposes of signaling.

Our invention of improvements in apparatus for employing electricity as an illuminating agent consists, firstly, in using horizontal levers attached rigidly to a piece or pieces of soft iron, serving as the armature of an induced magnet, made magnetic by the same current, which by its rupture in the space between the poles affords the light by which a vertical rod or beam or other contrivance for holding the electrode is gripped and held in a fixed position, but which rod is free to slide downwards or take any other course obligatory on the effect of gravity or the elasticity of a spring, the said levers serving the further purpose by their forming the armatures of an
4288 induced magnet of elevating or giving other direct motion to the rod when gript by them, the simplicity of the above

arrangement allowing for its modification in an infinity of ways. We claim especially as our invention the use of levers attached to the armatures of an induced mag-et or magnets to act in the manner and for the purposes described. Of the forms advised by us as the most convenient on the above principle we select the following, and which plan we recommend for all lamps in which the apparatus is likely to receive rough usage and where ornamental appearance and beauty of design are not required: The current enters by the binding screw A, figure 1 on sheet 1 of our drawings, and passes up the body of the lamp B through the magnet C C, which is secured to a bracket fixed to the pillar B. A wire, C′, is connected with the rod D in order to ensure better contact. This rod is suspended at E by the chain F and counter-poise G, which works within the tubular support B, but which is by no means necessary for the successful working of the lamp. The armatures H H are attached to brass levers, H′ H′, which are fitted with eyes, through which the rod passes freely when induction ceases, but when the current passes through the magnet the outer extremities of the compound levers H′ H′ are raised, and their eyes simultaneously grasp the rod D, which
4289 is thus held at a proper elevation, but when the current is
broken the levers assume a horizontal position and allow the rod to drop down, which effects a re-establishment of contact between the electrodes. A series of anti-friction pulleys are fitted at I to surround the rod and allow it to descend freely. The lower portion of the lamp corresponds to that shown at figure 1, sheet 2, of the drawings. Our improvements for employing electricity as an illuminating agent embrace also the construction of electric lamps in the manner and on the principles next described. The lamps constructed as below differ in form and principle from those described above mainly by the induced magnet being situate in the base of the lamp and by connecting the armature with the electrode carriers by a system of levers. This form of lamp may be made exceedingly ornamental, and will occupy but little space. A A, figure 1 on sheet 2 of our drawings, is an electro-magnet, which may be constructed in the form hereinafter described and shown in detail at figure 2, sheet 2, fixed in the base of the lamp, and rendered magnetic by the wires which enters at A′, the other end of the magnet being in connection with the base of the lamp. The armature B of the magnet is attached to the lower extremity of the rod C, which is attached at its upper end to one extremity of the lever D. This lever works on the fixed centre E, and is terminated by a fork, *f*, shewn more
4290 clearly in the plan view of the lever shown detached
at figure 3, drawn full size. The helical spring G serves to keep the end D′ of the lever elevated when the magnet is not in action. This fork embraces the collar H, which consists of two semicylindrical pieces hinged together at I and made to grasp the vertical rod J by the action of the ascent of the fork on the conical sides of the collar. The rod J is fitted with a socket, K, and tightening screw for holding the electrode L, which should be fixed rigidly to it. The lower electrode L′ is inserted into the socket M. This

socket is fitted onto the top of the main stand N, which also carries a binding screw, by which it is connected with the other pole of the battery. The black portions of the drawings represents the insulated points of the apparatus. Two flexible wires, *o*, connect the top of the lamp with the upper end of the rod J, to which they are secured by a binding screw, P. As the correct working of the lamp depends on the adjustment of the arc or striking distance between the poles during the working of the lamp, we introduce an arrangement which is marked by the letter Q, and which consists of a boss capable of turning round in a grooved ledge encircling the upper portion of the pillar, through which passes the rod attached to the forked lever D and the armature of the magnet B. The in-
4291 ner portion of the boss is grooved with a female screw-thread, into which works a male screw. The turning of the boss raises the ma*il* screw, which consists merely of a tube grooved on the outside and carrying the lever, causes the armature of the magnet either to recede or approach the poles, and hence decreases or increases the inductive power. Moreover, the portion of the pillar above the boss, being slotted to allow of the lever passing through, restrains the play of the lever to certain limits. These two circumstances combined serve as the required means of adjustment of the striking distance, as will be obvious without further description. The action of the lower pole of the lamp is as follows: The current which makes the electro-magnet A makes also the electro-magnet R before it passes to the general body of the lamp. The electro-magnet R attracts the armature S, which is attached to a curved lever moving horizontally on the axis T, but kept from the magnet during the time induction is not taking place by the spring U. At the other extremity of the lever is a movable tooth, V, but which after turning the rack-wheel X, into which it fits by the induction of the magnet, is always made to resume its original position by the bow spring V′. Y is a screw, which is made to rise and so elevate W, the electrode-holder, by means of the rotation of the wheel X. It will be clear from this description of the apparatus that the
4292 same action which results from the magnetic operation of A will induce a similar consequence in the action of R, with the exception that in the latter case the motion is a rising one instead of a descending one. Moreover, by the simultaneous action of both poles the great desideratum of preserving the light in one place is successfully accomplished. In addition to the mode just described of raising the lower electrode we claim also the means of effecting this by an arrangement in which, instead of a screw traveling within a tube, we use a long rack into which fits a tooth attached to a lever of the same kind and construction as the last described, but working vertically instead of horizontally, the induction of the magnet being downwards instead of laterally. The action of this arrangement is very simple and consists merely in the keeper at one end of the lever being attracted and so causing on every such occasion the opposite and toothed end to raise the rack a tooth when the inductive action takes place. The action of this lamp is as follows: The electric current on its passage through the magnet A causes

the armature B to be attracted, thereby drawing down the end D′ of the lever D and consequently raising the collar H and rod J, the electrodes being thus retained at a proper distance asunder so long
as a sufficient amount of attraction exists between the magnet
4293 and armature to keep the latter down. Should any non-
conducting material obstruct the passage of the electricity through the arc the induction of the magnet instantly ceases and the helical spring G coming into action forces up the end of the lever D and at the same time the descent of the forked end of the lever releases the grasp of the collar upon the rod J, which consequently slides down and re-establishes contact between the electrodes, the requisite arc being instantly reformed by the attraction of the armature, as hereinbefore described. If, as in other arrangements for producing the electric light, the contact be made by two or more points on the electrode, which points are temporarily removed to admit of the electrode sliding down as it burns away, the light will for such time go out and spark passing between the points of the jaws will fuse them, and hence in time from the coat of oxide formed the lamp will cease to be of any use at all, since the principle does not admit of good conduction being always kept up. The contact in our lamp is always the same and continuous, since the descent of the rod to which the electrode is attached requires simply a diminution of the friction exercised on the rod by the lever-and-collar apparatus hereinbefore described, and this we claim as the substantive part of our invention. This action is accompanied by no diminution of
the light. In addition to the forms described we pre-
4294 fer for public lights, and, indeed, for all cases of illu-
mination where the light has to be sustained for a long time, the use of several electrodes, and also the use of separate lights in the same lamp, but in all such cases we strictly adhere to the same principles and differ only in the mode of arrangement of the electrodes. In arranging several electrodes we take great care to preserve them insulated one from the other and deriving their electricity by separate wires. We occasionally oppose several small electrodes forming the positive poles to one larger electrode forming the compound negative pole of the several batteries. We find that by combining several electrodes or sources of light in the same lamp that if near together they prevent the chances of flickering, going out, sparks, &c., and render the general illuminative effect constant. Figure 4 on sheet 2 of the drawings is a partial section and elevation of an arrangement for raising the lower electrode A, and figure 5 is a horizontal section of the same. This is effected by the screw B, which is secured to the pulley C. A traversing nut, D, works in a slot in the side of the cylindrical case E, being raised or lowered by the screw B. The electrode A is fitted into a socket in the top of the nut and passes through the piece E, which serves to guide it in its assent. This arrangement, which must be worked
by hand, we substitute for the magnetic arrangement in the
4295 bottom of the lamp in figure 1 in all cases where the lamps

are used in situations where personal attention is practicable and easily attainable.

The next portion of our invention relates to electrical governors, indicators, and alar*u*ms, and other minor apparatus connected therewith. Figure 2 on sheet 1 of our drawings show- an arrangement for indicating any variation in the current, and also to a certain extent a means of measuring its intensity. We have termed this the electric governor or indicator. It is shown half in section and half in elevation. A is the base of the apparatus, to which is attached the single magnet B. A helical spring, C, is interposed between the magnet and armature D. A rack, E, is attached to the armature and takes in to the pinion F on the arbor of the indicator G. A wire, H, connects the armature D with the arbor of the indicator, and another wire, I, passes thence to the outer pole of the battery. The action is as follows: The current on passing through the magnet attracts the armature, drawing it down, more or less, according to the strength of the current, and consequently turning the pinion and with it the indicator G, which shows on the graduated dial the strength of the current. The helical spring is for the purpose of raising the armature when the
4296 attraction diminishes. Figure 3 on the same sheet of our drawings is an alarm or means of indicating at the battery depot or at any other place through which the electric mains may pass any sudden or partial cessation in the continuity of the circuit. It may be termed generally an alarm. A is an electro-magnet made by the same current of electricity that supplies the lamp or other apparatus. B is the armature attached to a lever, C, which is bent at right angles and carries a tooth detent at D, which fits the teeth of the ratchet wheel E. Attached to the centre of E as a radial arm is the rod F. G is a toothed lever hammer, of which the head I plays within the bell H, and is constrained to the position represented in the drawing by a co*a*l spring in the axle on which it works. K is a weight attached to a spring passing round a drum attached to the back of the ratchet wheel E. The action of the alarm is as follows: When from any failure in the current the armature B ceases to be attracted by the electro-magnet, then falling from its own weight it relieves the detent tooth D and the weight descending causes the ratchet wheel to rotate and so turn the radial arm F, which, striking the hammer G, rings the bell H. It is easy to see that the re-establishment of the current will instantly arrest the descent of the weight and therefore the ringing of the alarm by the induction of the keeper of the
4297 magnet to its former and fixed position. In order to increase or decrease the amount of light in the lamp when the illuminating apparatus is large or in order to adjust a powerful battery to a delicate lamp, we check the current as it enters by causing it to pass through iron wires of different thicknesses imbedded in pipe clay or alumina or asbestos, the connection being made by means of a handle of peculiar construction, which by sliding on an axis on which it turns over the top of the pipe-clay bed with the surface of which the iron wires are arranged parallel and flush the

current is passed through any one of the wires at the pleasure of the operator, thereby diminis-ing or increasing the intensity of the light given off at the points of the electrodes. Figure 4 is an end view and figure 5 a corresponding plan of this apparatus. A is a lever composed of ivory or any other good non-conducting material working on the fixed centre B and turned in a horizontal plane by the small handle C, and having a small metal stud, D, at the movable extremity. E F G H I are iron wires of graduated thicknesses resting in a bed of pipe clay, J, which is fixed in the wooden stand K. The terminals of the wires are united by the cross-piece of metal L, which is fitted with a set-screw, M, for the attachment of the wire N. The action of the instrument is as follows: The lever being turned so as to bring the stud D onto any particular wire, the
4298 current passing in at L travels by D along the upper surface of the lever A, which is of brass, and thence by the bind screw forming the fixed centre of the lever to the lamp. Now, if the current be found too strong all that is necessary is to turn the lever so as to bring the metal stud onto a wire of smaller dimensions, and so by the increased resistance retard the surplus power. As it will be evident that the power of a battery must after a certain time of action decline, and as such an event would seriously effect what might be taking place in the apparatus to which the electricity might be passing, such as the lamp, we have to overcome the difficulty by using in practice a reserve battery, the power from which we can instantaneously transfer by the following contrivance shown in elevation at figure 6 and in corresponding plan at figure 7: A is a disc of wood which may be firmly attached to any suitable support. B B′ B″ B‴ are metallic plates embedded in the disc, all on the same level; and having attached in the manner shown screws $x\ x'\ x''\ x'''$. In the centre of the disc is a boss, G, which is extended above into a handle, F, by turning which the two metallic arms E E′ *which* are attached to the boss G, but insulated from each other by the introduction of a piece of ivory or other good non-conducting material. On the arms E E′ are two binding screws H H′. The action of the apparatus is very simple, and is as follows: The battery in action and the battery in reserve
4299 are attached by wires to the four metallic plates B B′ B″ B‴ by means of the binding screws. Thus to B B′ is attached the battery in action, which we will term a, and to B B′ accordingly are turned the metallic arms E E′, the current then passes by wires attached to the binding screws E E′ direct to the lamp or other apparatus. Now, supposing the power of a to be declining from the length of time the light has been burning without causing any cessation in the production of the light, all that is necessary is to turn, by means of the handle F, the metallic arms E E′ to the metallic plates B″ B‴ by sliding over and on to which the reserve battery, which we will call b, is immediately brought into play and the electricity from the fresh source instantaneously applied. The battery is then at liberty to be replenished and prepared for taking b's place when b shall have been exhausted. By such

means the light may be maintained with sufficient length of electrodes for a week in action without cessation. It is often desirable suddenly to change the poles when either from want of homogeneity in the electrodes or from any accidental cause one electrode has consumed much quicker than the other. This we effect by what we term the "brake," a small apparatus consisting of a sliding plate of brass or other metal, which being slid over 4 buttons of brass, each button forming the terminal of either the battery poles or the lamp
4300 poles, the current is made to proceed through the negative pole of the lamp or the positive pole, as the case may be. Let A and B, figure 8, be the positive and negative poles of a galvanic battery; a' b', the poles of the lamp; then let it be required to change the poles of the lamp. $x\,x'\,x''\,x'''$ are metallic plates well insulated from one another and arranged in a line in a wooden stand. L L′ is a slide consisting of wood and with two metallic ends and moved by the handle C. Now, when the ends of L L′ are on the plates $x\,x''$, then the current setting out from the positive pole of the battery (A) circulates by the wire 1 to the positive pole of the lamp a' by the wire n and returns by n' to x'' and thence by the wire 2 to the negative pole of the battery (B). To change the poles of the lamp the slide is slid back to $x'\,x'''$, and then the current from A circulates by 3 to x''', thence to b', and by 4 back from x' to B, by which b' becomes positive, a' negative; in other words, the poles of the lamp are reversed. Occasionally we employ electro-magnets of the following description, which we form as follows: A copper band 4 inches broad and about 25 feet long is insulated by coating with calico. A portion 3 inches long of this piece is then bent back, and between it and the main piece is inserted a plate of soft iron, the band 2 inches of which is next bent back in the opposite direction and a similar plate of soft iron inserted as before.

The rendering of this dry plate magnetic is effected by pass-
4301 ing the current in the direction indicated by the arrows in the drawing, by which double the opposite poles are obtained in the same plate. In the drawing, figure 2, sheet 2, A is a brass plate. B B′ are the copper plates. $x\,x'$ are the wires bringing the current which renders the pile or flat helix magnetic. The black spaces represent the iron plates. C is the keeper. It will be obvious to the practical man that the hereinbefore-described arrangements are equally applicable to signalising purposes.

Another portion of our invention relates to the use of two or more electrodes in the same or different planes and the arrangement of such electrodes so as to produce more than one point of illumination in the same lamp at the same time. Our improvements in the nature and manufacture of electrodes are as follows: Causing them to be homogeneous, moderately hard, of perfect conduct*a*bility, suffering moderate and perfectly uniform convection during ignition and non-absorbtive, as far as possible, of moisture. Under this head we have effected our improvement in the following manner: We have found that by taking 70 parts of finely powdered coke well boiled in nitro-muriatic acid to remove any metallic or earthly impurities with which it might be contaminated and afterwards wash-

ing it with caustic posash, that by taking this and washing it with 20 parts of red charcoal (we prefer it from the beech), or, as it is termed by French, charbon rouge or ani-
4302 mal charcoal, and 5 parts of gas pitch with 4 parts of
finely powdered Newcastle baking coal and 1 part of china clay, that by thoroughly incorporating the mass the desired end is obtained by subsequent careful heating in a mould of appropriate construction. We generally prepare a mass of about 1 foot 6 inches broad and 3 feet deep at a time, the gases which are reduced by distillation being allowed to escape by an induction pipe. The time occupied for the preparation of the mass we prefer to be nine to twelve hours, the heat being applied very gradually for the first two hours, after which the mass is tightly compressed by the ends of the mould being made to approximate by means of a screw. The furnace for heating the mould may be of any suitable description. After the mass is withdrawn from the mould and cooled, if the operation has properly been conducted, it may be sawn into pieces of the desired size, perfectly homogeneous in their structure. We have found that good electrodes giving a steady achromatic light may be prepared by the following process from well-burnt beech charcoal, selected from the small wood, or, as they are technically termed, "loppings;" boxwood will do as well: A piece of the charcoal sawn into required size for the electrodes is steeped in a solution of caustic lime for about a quarter of an hour; it is then taken out, dried, and placed into a crucible containing powdered
4303 charcoal, and, a lid being firmly and closely luted onto the
crucible, it is exposed to a white heat for about half an hour; it is then taken out after the crucible has cooled, placed into a saturated solution of alum, and after having soaked for about half an hour it is dried, and again brought to a white — as before. It is again removed and plunged whilst hot into treacle or any thick saccharine or carbonaceous fluid and finally once more ignited. If the operation- have been properly conducted it is now very hard, quite free from any traces of lignious structure, a perfect conductor, and burns moderately slowly, equally, and nois-lessly when forming the terminal of the voltaic arc. The electrodes which are formed by the first-described process burn at the rate of about a quarter of an inch an hour on an average, so that an electrode a foot in length would burn between twenty-four and twenty-eight hours. They consume evenly and are but little effected by the wind. Before using, the electrodes are pointed by a fine file in order that they may wear equally after being first ignited. For electrodes which are intended to be used in lamps where the arc will be great and the current passing very powerful we use instead of alum soluble glass, which is prepared in the following manner: 15 parts of powdered quartz or very fine sand are fused with 10 parts of potash and 1 part of charcoal in a crucible. When the fusing is complete the crucible is uncovered and the mass taken out and treated with cold water, by which the extraneous particles of carbon and foreign salts
4304 are removed. The residue is then heated with hot water
and thereby entirely dissolved. The electrodes are im-

mersed in this from five to ten minutes whilst the solution is hot. The other operations for preparing the electrodes are the same as in the preceding case. The object of adding the non-conducting substances, alum, china clay, soluble glass, and caustic potash, is to prevent the excessive convection which the otherwise great conductability of the carbon would occasion and thereby render the continuity and perfection of the light impossible from the excressences formed about the poles.

Having now described and particularly ascertained the nature of of our said invention and the manner in which the same is or may be used or carried into effect, we would observe, in conclusion, that we do not confine or restrict ourselves to the precise details or arrangements which we have had occasion to describe or refer to, as many variations may be made therefrom without deviating from the principles or main features of our invention, but what we consider to be novel and original and therefore claim as the invention secured to us by the hereinbefore in part recited letters patent is—

First. The general construction and arrangement of electric lamps as hereinbefore described.

Second. The application and use of a conical collar constructed of two semi-conical pieces of metal hinged at one of their extremities and acting as a grip upon a solid rod carrying the upper
4305 electrode of an electric lamp as hereinbefore described.

Third. The application and use of a lever forked at one of its extremities to act upon the conical collar in the manner and for the purposes hereinbefore described.

Fourth. The connection with one extremity of the aforesaid lever of the armature of an induced magnet to act in the manner and for the purposes hereinbefore set forth.

Fifth. The attachment of a spring in the manner hereinbefore described to the aforesaid lever to cause the forked extremity of the lever to leave the sides of the conical collar during the momentary cessation of the induction of the magnet in the manner hereinbefore described.

Sixth. The regulation of the striking distance by the slot and traveling screw-boss shown in figures 4 and 5, sheet 2 of the drawings, in the manner and for the purposes hereinbefore described.

Seventh. The construction and use of the screw for raising the lower electrode in the manner and for the purposes hereinbefore described and shewn in figure 1 on sheet 2 of the drawings.

Eighth. The use and construction of the horizontal levers forming the armature of an induced magnet or magnets for gripping the electrode holder in the manner and for the purposes hereinbefore described.

Ninth. The system or mode of raising the lower electrode in the manner and for the purposes hereinbefore described and
4306 shewn in figure 1 on sheet 2 of the drawings.

Tenth. The use and application of an electro-magnet for turning the ratchet wheel giving motion to the traveling screw holding the lower electrode in the manner hereinbefore described.

Eleventh. The system or mode of applying electric currents, so

as to cause a more equable consumption of the electrodes, in the manner and for the purposes hereinbefore described.

Twelfth. The making of the two electro-magnets inductive at the same time and by the same current that supplies the light.

Thirteenth. The use of helices of copper or other wire in lieu of electro-magnets in the manner and for the purposes hereinbefore described.

Fourteenth. The application and use of several electrodes in the same lamp as arranged in the manner hereinbefore described.

Fifteenth. The construction of electro-magnets in the manner hereinbefore described and shewn in figure 2 on sheet 2 of the drawings.

Sixteenth. The construction of the governor and indicator for indicating the variation and strength of the current in the manner hereinbefore described and as shewn in figure 2, sheet 1 of the drawings.

Seventeenth. The use and construction of the alarum shewn in figure 3, sheet 1, in the manner and for the purposes hereinbefore described.

Eighteenth. The use and construction of the apparatus for retarding the passage of the current entering the lamp in the man-
4307 ner and for the purposes hereinbefore described and shewn in figures 4 and 5 on sheet 1 of the drawings.

Nineteenth. The construction and use of the apparatus for changing the passage of the current passing to the lamp or other apparatus, or as applied in any way practically from one battery to another, as hereinbefore described and as shewn in figures 6 and 7 on sheet 1 of the drawings.

Twentieth. The construction and use of the apparatus called "the brake" in the manner and for the purposes hereinbefore described and as shewn in figure 8 on sheet 1 of the drawings.

Twenty-first. The formation and use of electrodes of the materials and in the manner and for the purposes hereinbefore described.

Twenty-second. The introduction into the electrodes of a certain amount of non-conducting material to check the excess of convection and to render the light properly achromatic in the manner hereinbefore described.

Twenty-third. The introduction into the composition of the electrodes of a certain amount of caustic alkali or earth in the manner and for the purposes hereinbefore described.

Twenty-fourth. The application and use of the electric light for the purpose of signalizing.

In witness whereof we have hereunto set our hands and seals the fourth day of April, one thousand eight hundred and fifty-three.

Specification of Martyn John Roberts.

Obtaining light, motion, &c., by the agency of electricity.

London: Published and sold at the patent office sale branch, 38 Cursitor street, Chancery lane, E. C. 1888. Price, 1s. 3d.

4311 (Fourth edition.)

A. D. 1852. No. 14198.

Obtaining Light, Motion, &c., by the Agency of Electricity.

Roberts' specification.

To all to whom these presents shall come I, Martyn John Roberts, of Gerrards Cross, in the county of Bucks, gentleman, send greeting:

Whereas her present most excellent majesty Queen Victoria by her royal letters patent under the great seal of the United Kingdom of Great Britain and Ireland bearing date at Westminster the sixth day of July one thousand eight hundred and fifty-two in the sixteenth year of her reign did for herself her heirs and successors give and grant unto me the said Martyn John Roberts my ex'ors adm'ors and assigns her especial license full power sole privilege and authority that I the said Martyn John Roberts my ex'ors adm'ors and assigns or such others as I the said Martyn John Roberts my ex'ors adm'ors or assigns should at any time agree with and no others from time to time and at all times during the term of years therein expressed should and lawfully might make use exercise and vend within England Wales and the town of Berwick-upon-Tweed my invention of "Improvements in the production of electric currents in obtaining light, motion and chemical products and effects by the agency of electricity, part or parts of which improvements are also applicable to the manufacture of certain acids and to the reduction of ores" In which said letters patent is contained a proviso that I the said Martyn John Roberts shall cause a particular description of the nature of my said invention and in what manner the same is to be performed by an instrument in writing 4312 under my hand and seal to be enrolled in her majesty's high court of chancery within six calendar months next and immediately after the date of the said in part recited letters patent as in and by the same reference being thereunto had will more fully and at large appear.

Now know ye that in compliance with the said proviso I the said Martyn John Roberts do hereby declare that the nature of my said invention and in what manner the same is to be performed are fully described and ascertained in and by the following specification reference being had to the drawings hereunto annexed for the purpose of illustrating the description of certain parts thereof (that is to say)

My improvements in the production of electric currents consists in a mode or modes of obtaining such currents at a cheaper rate or more economically than hitherto done by repeatedly used or applying certain materials in the production thereof For this purpose I take the products of a battery or batteries such as hereafter mentioned that is to say the products of the chemical action in the battery (such as hereinafter mentioned) by means of which an electric current has been produced and I convert such products into the materials from which they have been formed or into a state similar to that in which they existed when introduced into the battery The materials so obtained may then be again used or employed in a galvanic battery for the production of electric currents as before and so alternately may the materials be used in producing electric currents and the produce of the process reconverted into its original materials without further diminution than the waste which is necessarily occasioned by the performance of every process When I use a galvanic battery in which platina is the negative plate and iron the positive plate and excite these by nitric acid to generate currents of electricity part of the acid is itself decomposed yielding a portion of its oxygen to the iron so as to convert it into oxide of iron the other elements of the decomposed acid being given off in the shape of fumes of nitrous or hyponitrous gas or other combinations of oxygen and nitrogen Another part of the nitric acid will combine with the oxide of iron and form nitrate or pernitrate of iron. The fumes above mentioned I convey into any convenient vessel and convert them (with as little loss as possible) into nitric acid For this purpose I add to them such a quantity of oxygen or of atmospheric air containing the quantity of oxygen requisite to convert the fumes into nitric acid I then bring the combined gases into contact with as large a surface of water as practicable which will cause a chemical union of the gases so as to form nitric acid which will then be absorbed by the water. I also take the nitrate or pernitrate of iron the other product of the battery and place it in a retort and
4313 apply heat until the whole of the nitric acid has been distilled into a receiver containing water and the vessel used for combining the nitrous fumes and oxygen may conveniently be used as a receiver for that purpose. The residue left in the retort will be oxide of iron which I convert into metallic iron by smelting it with carbon in the usual way By these means the above mentioned products will be reconverted into the same materials as were originally introduced into the battery and those reconverted materials may be again applied in a battery for the production of electric currents and by these means a very considerable saving may be effected in the cost of producing the electric currents When any other metal

shall be used as the positive plate in conjunction with nitric acid as the exciting fluid I treat the products of the battery in a similar manner When I employ a battery consisting of the same plates as above mentioned using sulphuric acid as the exciting fluid the product obtained from the battery will be a sulphate of iron The sulphate of iron thus obtained I place in a retort and apply heat until the whole of the sulphuric acid shall be driven off into a receiver in the ordinary way The residue in the retort will be oxide of iron which I convert into metallic iron by smelting with carbon as above described.

This part of my invention is also applicable to the reduction of ores at a cheaper rate or more economically by repeatedly using or applying certain materials in the reduction thereof by means of electric currents Thus when nitric acid is applied to a copper ore so as to form a nitrate of copper and that nitrate is then decomposed by means of any other suitable metal and an electric current so as to obtain metallic copper nitrous fumes and a nitrate of the metal employed will be formed in like manner as above mentioned These products I treat in like manner as above described and thus regain the metal and the nitric acid to be again applied in like manner as before. So also if sulphuric acid be applied to copper ore so as to obtain a sulphate of copper and that sulphate be then decomposed by means of iron and an electric current for the purpose of obtaining metallic copper the resulting sulphate of iron may be treated in like manner as above described.

I have also invented an apparatus applicable to the purpose of causing the combination of nitrous acid gas and other compounds of nitrogen and oxygen with a further quantity of oxygen so as to form nitric acid and also for the purpose of causing the absorption of such nitric acid by water such apparatus is also applicable in the manufacture of such other acids as are formed by the union of two or more gases by promoting the union of such gases and causing the acids when formed to be absorbed by water This apparatus consists of a pipe or series of pipes opening freely
4314 from one into the other and filled with flints or some substances not easily acted on by the acid passing through them Through these pipes a current of water is made to flow so as to keep the surfaces of the flints or other substances covered with water and expose as large a surface of water as possible to the action of the gases passing through the tubes The water exposing so large a surface will thus be enabled more rapidly to absorb the gas or gases which it can take up and also more effectually to assist in the combination of gases in those cases in which water may be requisite for that purpose And when it shall be intended that the water shall contain a saturated or strong solution the same water may be caused repeatedly to pass through the tubes until the desired result has been attained When I employ this apparatus for the purpose of converting the fumes arising from a battery into nitric acid as above mentioned I convey these fumes by a tube into the pipes of the apparatus and into this tube and amongst the fumes I inject oxygen gas derived from any source but I prefer as most economical to in-

ject atmospheric air by bellows or other convenient apparatus this air is with the fumes driven along them into the pipes of an apparatus where it will come into contact with the moisture and a combination of the acid fumes with the oxygen will take place thus forming nitric acid the water absorbing the nitric acid will carry it down in a liquid form to a reservoir below the pipes figure 1 shows the apparatus A A A is a series of glass tubes opening at the bottom into one common reservoir R this reservoir is filled with water to above the mouth of the pipes as shewn by the dotted line and seals them air tight as regards these lower openings but the tubes have a free air or gas passage from one to the other at bottom as shewn by the small pipes *p p p* And at the top the large pipes open one into the other by their curved heads The intention being to have an air or gas passage from A × at the beginning of the set of pipes to A × the end of the pipes A. A. A. or orifice opening freely into the atmospheric air. Above the pipes A A A is another water or acid reservoir R X and from this small syphon tubes S S S convey acid or water into A A A and yet to prevent gases or air passing through them into the reservoir R × they being always filled to a certain height with liquid The end A × of the set of pipes A A A joins to the main pipe M leading to the battery and the battery being closed in on every other side the fumes must pass though M into A A A At B a pipe B × joins M. B × is in connection with a bellows or other apparatus for supplying atmospheric air A syphon pipe with water or a valve is interposed between B and the bellows to prevent any escape of the gases backwards through the bellows Let
us now suppose the two reservoirs R and R × to be filled
4315 with water to the dotted line the battery in action pouring
its fumes into M while the bellows through B × is injecting atmospheric air the fumes and the air mix and are driven into A A A here they meet with a very extensive wet surface of flints which causes the oxygen of the air to combine with the battery fumes and the current of water carries down the condensed fumes in the form of liquid acid into the reservoir R the nitrogen of the air and that part of its oxygen that did not combine with the fumes is driven out at the end of the pipes at A × × but in no case have I found any acid fumes lost at this opening when the series of pipes were long enough and the flow of water through the pipes continuous I have found that if the total length of the series of pipes exceed 35 or 40 feet long and 2 inches in diameter no loss of acid fumes was occasioned from want of condensing power The acidulous liquor in the reservoir R may either be removed of if wished to be made stronger may be raised by pump or otherwise to the reservoir R × from whence it may pass a second time through A A A and acquire a second dose of acid and this can be repeated until the desired strength of acid is obtained.

I desire it to be understood that I do not claim the elements or component parts of the apparatus which I have described separately or a part from the combination thereof in manner aforesaid and that what I do claim with reference to this part of my invention is, the combination of parts forming the apparatus hereinbefore described.

Another part of my said invention consists in a pecular mode of applying or using lead as a positive metal or plate in a galvanic battery When a plate of lead is used as the positive plate in the usual manner if the circuit or channel which leads from one pole of the battery to the other be broken for a short time when the circuit is again completed the current of electricity generated by the battery is found to be much diminished I have discovered that if a second or supplemental circuit or channel be opened or in other words if the current of electricity is allowed to flow through a second circuit while the main or principal circuit is broken the main current may be re-established without any material diminution of the electric current produced by the battery The secondary circuit which I prefer to use for the purpose of preventing the powers or currents produced by a leaden battery being diminished I form partly of a dilute acid (contained in any convenient vessel) and partly by a wire proceeding from each pole of the battery the termination of such wire (in the dilute acid) being composed of a platina plate in the ordinary way this secondary channel is in constant connection with the battery but the resistance which it is made to oppose to the electric current is so adjusted (by regulating
4316 the distance between the platina plates or otherwise) that it
shall always be greater than the resistance which the current meets with when flowing in the main channel or circuit so that when the main circuit is unbroken no current of electricity shall take place through the secondary channel, but immediately the main circuit is broken the electricity will flow through the secondary circuit which will thus maintain the current so that the battery may be ready for action in its full strength whenever the main circuit shall be made perfect With respect to this part of my invention I claim the use or addition to a battery in which lead is used to form the positive plate of a second or supplemental circuit or channel in manner and for the purpose hereinbefore described

My improvements in obtaining light by the agency of electricity consist firstly of a mode or modes of adjusting or regulating the distance between the points of the two electrodes used in the production of electric light so that the points of those electrodes shall be maintained or from time to time replaced at the proper distance from each other for the production of light which is usually called the striking distance The mode in which I effect this object is to arrange the apparatus carrying one of the electrodes so that such electrode shall be released from such apparatus and allowed to fall down or move forward until its point comes in contact with the other electrode and then be again taken hold of by the apparatus within which it is placed. This object having been effected I then by means of another arrangement of the apparatus either in connection with the same or the other electrode, draw back one of the electrodes until the points of the two electrodes shall be the proper and regulated distance from each other as above described The apparatus for producing these effects may be actuated either by an electric current or by mechanical means such as usually termed clock work And in the drawings hereunto annexed I have shown apparatus for effecting the above mentioned objects actuated or having motion given to it by an electric current and also apparatus for effecting the like objects worked by clock work

In figure 2 A A is a board or stand on which an upright pillar B of brass and about one inch in diameter and 18 inches high is firmly secured to the stand the pillar is bent at top into a right angle forming a projecting arm *c* of about 8 inches long to this is soldered the rod D about 6 inches long which forms a support and guide for the tube E which is $\frac{3}{8}$ inch internal diameter and about 12 inches long E is furnished with two pins × which slide in guide holes *o* and by these E is guided into a vertical motion when made to slide up and down E is in metallic connection with the pillar B by means of the flexible metallic strap F for the purpose of conveying electricity to it from a galvanic
battery which electricity traverses a wire that encircles
4317 an electro magnet M hereinafter to be described The tube
E contains a graphite or carbon electrode which electrode is from 8 to 12 inches in length or longer if convenient and of such a diameter as to slide freely within the tube E and yet not to fit so loosely as to fail to be pressed by the spring mouth piece S which mouth piece is a segment of the mouth of the tube E furnished with a long spring S × so far removed from the extremity of E that the heat of the incandescent graphite shall not injure it. The use of this spring mouth piece is to press against the electrode and give good metallic contact between it and the tube for the certain conveyance of electricity to the electrode and for further ensuring this the mouth piece is lined with platina but the mouth piece does not press against the electrode so forcibly as to prevent the graphite sliding through it either by its own weight or better by aid of a spring or small additional weight placed behind thus the electrode would always fall through the tube E were it not supported in it by the pressure of two jaws or clips F^1 F^1 working on joints or hinges G G The ends of these clips entering through two slits into the interior of the tube E and pressing so firmly (when in action) upon the electrode as to prevent its sliding and keep it securely in its place, these clips are actuated by two rods as handles *h h* reaching to the top of the tube E and there connected by a joint with a lever L if the other end of the lever be depressed it draws up the handles *h h* and the clips bite inwards upon the graphite or other electrode within the tube The lever L at the end Q is by a joint and rod N attached to a bell crank P the other limb of the bell crank is fixed to the piece of iron K that serves as a keeper to the electro magnet M This electro magnet is of the usual kind vizt a bar of soft iron in the horse shoe form wound round with a coil of covered copper wire and this wire forms part of the electric channel or circuit from one pole of a galvanic battery to the other, one end of this coil is soldered to the pillar B the other end has a binding screw for the purpose of attachment to the wire leading to the positive pole of a powerful galvanic battery On the base or stand A and vertically under the tube E is a socket R for the purpose of holding another graphite electrode T and the socket by means of a binding screw

can be put into good metallic connection with a wire from the negative pole of the galvanic battery by three slots and screws the socket and its electrode can be so adjusted as to bring the points of the electrodes in exact contact with each other Let us suppose the lamp now ready for action one graphite electrode in the socket R another dropped into the tube E the clips being open by reason of the balance weight W on the end of the lever L depressing the end of L and forcing the clips open the electrode in E slides through until its point comes into contact with that in the socket
4318 R if the lamp be now put into connection with the battery the
electricity circulates round M making this a powerful magnet attracting the keeper K this draws down the lever L raises the handles of the clips *h h* the clips seize on the electrode within the tube holding it firm while the further depression of the lever L lifts up the tube E until stopped by the adjusting screw *z* generally for the distance of $\frac{1}{32}$ of an inch while this is taking place the electricity circulates from the coil round M through the pillar B the strap F the metal of the tube E and to the electrode within it this electrode has now been raised by the lever L as described $\frac{1}{32}$ of an inch and consequently so far separated from the electrode in R and the electricity passes from the point of the electrode in E to that in R giving an intense light from R it circulates by means of a wire to the other end of the battery While this is taking place the electrodes gradually waste away until a time arrives when the distance between the points of the two electrodes is too great for the electricity to surmount or pass through immediately this occurs the current of electricity ceases M is no longer a magnet the keeper is released the lever L by means of the balance weight W is depressed at the end in connection with the clips of the tube E descends its allotted space the clips open and the electrode in E is free to slide downwards which it does until it comes into contact with the electrode in R the instant this contact takes place the circuit is complete again the current of electricity circulates and the same action as that first described with the evolution of a brilliant light takes place until by another wasting of the electrodes the same change ensues and this is repeated again and again until all the electrode is destroyed I find that with a moderately powerful battery about one and a quarter inch of electrode wastes per hour.

The construction of electric lamps may be modified in various ways so as to cause the distance between the two electrodes to be from time to time during the turning of the lamp adjusted or regulated in manner hereinbefore described In one modification of my lamp I cause the distance between the electrodes to be from time to time adjusted or regulated by an apparatus of a more simple description than that just described Figure 3 shows a side view or elevation of this machine A B and C are the stand pillars and arm similar to those of the lamp before described in figure 2 from C a rod D as before guides the motion of the tube E in the manner before described near the centre of the arm C is a fulcrum on which an electro magnet M can vibrate on its pivot the electrode in the tube E is provided with an iron holder or handle H which may be

attached to the electrode or merely rest on it as a weight which slides within the tube E but projects above it even when its lower
end is near the mouth of E The handle when thus in the
4319 tube E is close to the pole of M or to both poles if M be a
horseshoe magnet but it is prevented from coming into absolute metallic contact by a covering of some non-magnetic substance either on H or on the pole of M for the purpose of preventing it sticking by the residual magnetism in M The tube E is attached to M by a link or strap *a* and above the pole of M is fixed a piece of iron I so near as to attract and raise M when M is a magnet. E is in good electric connection with the battery by the wire coiled round the electro magnet and the strap or rod leading from it to the binding screw X and the arrangements for the lower electrode and the mouth-piece of the tube are the same as described in figure 2.

Now the action of the apparatus is as follows Suppose the lamp not in connection with the battery. M is not a magnet the handle or weight H is therefore free to slide downwards in the tube by its own weight and carries before and with it its electrode until the electrode comes into contact with the lower one Immediately contact is made with the battery M becomes a magnet seizes hold of H and at the same time attracting and being attracted by the iron I the end of the magnet and the tube E attached to it is thus lifted up until stopped by the regulating screw U the electrodes being thus separated a short distance from each other the electricity passing between them gives out brilliant light until the electrodes having so far wasted that the distance between them is too great, M ceases to be a magnet drops itself and the tube E at the same time releases the holder H which slides downwards until the two electrodes are once more in contact with each other the current of electricity is re-established when M becomes once more a magnet and the same series of operations as first described takes place

In all the modifications of my electric lamps if a single tube and pair of electrodes be used the quantity of light is apt to vary with the varying distance of the points of the electrodes caused by the wasting away of each until the striking distance becomes too great when as before described a fresh portion of electrode is protruded To avoid this inequality of light and obtain a fair average I (in some cases) use two or more sets of electrodes combined within the same lamp and either worked by one battery or by more This arrangement permits one pair of electrodes to be at their maximum production of light while another pair is at their minimum production and thus between the two a good and equal average quantity of light may be obtained and if two such lamps or pairs of electrodes be used in connection with one battery as the light produced from one pair of the electrodes diminishes in consequence of the increased distance between their points that pair of electrodes obtains a less
quantity of electricity from the battery and the surplus or re-
4320 mainder is sent through the second pair of electrodes thus
increasing the light which they produce.

In figure 4 I have shewn an arrangement of clock-work apparatus by means of which I cause the distance between the two electrodes

of a lamp to be from time to time adjusted or regulated A stand A has a pillar B to which a tube C of about twelve inches long and three eighths of an inch bore is screwed this tube is also furnished with a spring mouth piece C^1 as described in figure 2 a slot or opening of about an inch long is made in the tube about an inch above its mouth, through this slot the short arm X of a bell crank lever L can enter for the purpose of pressing upon and arresting the descent of an electrode withine the tube the lever L works upon pivots *p p* and the end L^1 (being heavy) when free to move falls downwards pressing its short arm through the slot in C On the same stand and turning on proper supports or pillars H is a wheel *w* of about four or five inches diameter a segment of this wheel is cut off as shewn at *a a* upon the axle of the wheel is an arm F which when the wheel axle is turned strikes against the lever L and raises it of course at the same time causing the bent arm X of the lever to come out of the slot by this action the electrode within the tube before supported by X falls by its own weight or assisted by any spring or weight behind it Above the wheel is another lever R working on pivots at I and pillar T and the end of this lever immediately over the wheel rests upon its periphery. Now if the wheel be turned the lever (if the wheel be round) remains at rest until that part of the wheel which is reduced or cut off comes below the lever when the lever follows this irregularity in the wheel and consequently becomes depressed at that end raising the other Now to the end Q of the lever R is attached by a link or strap P a socket S which is free to slide perpendicularly up and down upon a proper guide or support z this socket contains the lower electrode E × and is in metallic connection by a flexible strap with a binding screw K to connect it with one end of the battery. the electrode within the tube is also in connection by means of the tube and pillar with the battery which can be joined on to it by the screw K × a carbon electrode is put into the socket S and another into the tube C and if the wheel is turned until the depression in the periphery of the wheel is under the lever R this falls and raises the lower electrode to its normal place at the same time the arm on the axle raises the end of L which frees the electrode in the tube C and this electrode falls into contact with the lower electrode. The apparatus being put into connection with the battery and the wheel turned by proper clock work attached to its axle the arm F passes the lever L which drops and secures the electrode within C the periphery of the wheel
4321 now raises the lever R depressing the lower electrode until
a proper striking distance is obtained the wheel revolves until the lower electrode is again raised to its normal place the arm strikes the lever L liberates the electrode in C and a repetition of the described operation takes place at every separation of the electrodes a vivid light takes place between these points and the duration of the light is while the wheel maintains them apart (of course if not so long as to waste the electrode too far) and the duration of darkness while the points of the electrodes are in contact.

This apparatus I deem to be applicable as a light for lighthouses by causing the electrodes to remain a longer or shorter time in contact with each other the light may be made intermittent and the intermission regulated at pleasure so as to have the desired durations of light and darkness respectively for indicating the particular light house to which it belongs

With respect to machines or apparatus for producing light as hereinbefore described I claim as of my invention the construction of electric lamps with apparatus attached thereto whereby the points of the electrodes shall be from time to time brought into contact with each other and then removed to a proper or striking distance apart in manner and for the purposes hereinbefore described.

Another part of my invention consists of a mode of obtaining electric light by passing a current of electricity through a thin piece of graphite coke or charcoal or other infusible body being a conductor of electricity while it is enclosed in a vacuum or space not containing any oxygen or other matter which can cause the combustion or destruction of it when brought into an incandescent state by the action of the current of electricity.

In figure 5 I have shewn an elevation or side view of an apparatus which may be used for this purpose but I desire it to be understood that I do not claim any of the elements or parts of which this apparatus is composed apart from the combination thereof In this figure A is a stand upon which a hollow pillar or tube B can be screwed this tube is furnished with a stop cock S by which its passage can be closed air tight on the top of the pillar is a screw C about one and a half inch in diameter which receives the neck of the globe G also furnished with a cap and screw to allow it to be screwed air tight down upon the tube B The tube B has a binding screw F soldered to it for the purpose of making connection with a galvanic battery and the tube is also in metallic connection with a rod R having at the end of it a clip H for the purpose of holding a piece of graphite or other substance through which I wish to pass the electricity another rod R^1 also furnished with a similar clip H × passes through the head of the pillar or tube B but
4322 is preserved from coming into metallic contact with it by
having the rod enveloped in ivory at D or other non-conductor of electricity At the bottom of the rod R^1 is another binding screw F × for the purpose of connecting it with the other pole of the battery Now the mode of operation with this apparatus is as follows—a piece of very thin graphite about half an inch long half an inch wide and as thin as conveniently can be made is fastened at each end into the clips H and H^1 and firmly secured, the globe G is screwed air tight upon the pillar B the stop cock S is opened and the whole apparatus by a screw at the botton of B screwed down upon an air pump or exhausting syringe by this the air is drawn out of G and as perfect a vacuum as can conveniently be made obtained, when this is done the stop cock is shut and the apparatus is then removed from the pump to its stand A and a galvanic battery is put into connection with it by the binding screws F F × the electricity passes through the rods and thin piece of graphite J which becomes white hot from the passage of the electric current and no combustion will ensue if the vacuum be perfect

and no matter within the globe to cause combustion of the graphite or if the graphite be not otherwise destroyed the light continues as long as the electricity flows through the graphite in sufficient strength.

And with respect to this part of my invention I claim the production of light by passing electricity through a thin infusible body being a conductor of electricity in manner hereinbefore described.

Another part of my invention consists of a mode or modes of giving increased brilliancy to the light produced by electric lamps.

I have discovered that flame or the combustion or volatilization of some substances between or on the points of the electrodes will very much increase the light produced by an electric lamp Thus if a candle or lamp be placed so that its flame shall pass between the points of the electrodes the brilliancy of the light evolved between the electrodes will be increased And if lime or any other alkaline earth be interposed between the points of the electrodes when the lamp is in action the brilliancy of the light evolved will be very greatly increased When I intend lime to be interposed between the electrodes in this manner I prefer to effect that object in the same manner as lime is introduced between two jets in what is usually called the Drummond light I prefer however to produce the same or nearly the same effect by a new description of electrode which I make by mixing the material of which the electrodes may be composed with a portion of lime or other alkaline earth (I have used about five per cent of lime with success) taking care not to introduce as much as will materially diminish the power of
4323 the electrodes to conduct electricity When electrodes thus
made are brought into action in the lamp they produce a light very much more brilliant than electrodes made without any such admixture.

Another part of my said invention consists of a mode of diminishing the spark produced upon the breaking of a circuit for conducting currents of electricity It has been found that when a current of any great power has been employed the points or parts at which the circuit is broken are rapidly destroyed by the spark produced by breaking circuit For the purpose of avoiding or preventing this evil immediately before the breaking of the circuit I furnish the current of electricity with another circuit which is shorter so as to destroy or greatly diminish the electric action by which the spark is created at the place where contact is broken The formation of such a secondary circuit will of course carry off the greater portion at least of the electricity which would otherwise pass along what may be called the primary or working circuit or channel And in some cases this diversion of the current of electricity from the primary or working circuit or channel may be a sufficient substitute for the breaking of the primary circuit If the primary circuit be broken I cause it to be again made before breaking the secondary circuit so that upon breaking the secondary circuit there shall always be another circuit for conducting the current of electricity and so preventing the production of a spark or greatly diminishing it The making and breaking of this secondary and short circuit may be effected by means of any ordinary contact breaker used in electro-galvanic apparatus care being taken to construct or regulate it in such a manner that it shall make and break the secondary circuit at the proper times or intervals

I will now describe my apparatus for making and breaking contact when the primary or working channel is also made and broken

A stand A figure 6 supports a pillar B of metal having a binding screw E^1 to connect it with one pole of a battery To the top of this pillar a metallic spring P is soldered and at the end of this a piece of iron I to act as keeper to the small electro-magnet M another metal pillar D is fixed to the stand and can by its binding screw be put into connection with the electro-magnet M a third pillar E on the same stand can also by its binding screw be put in connection with the other pole of the battery the N°s 1. 2 shewing the poles to which all are to be connected On the pillar E a lever L in metallic connection with E moves on a pivot *p* and is so arranged as to press by its spring × its end onto the top of D. A wire from D is coiled round and forms the coil of the electro-magnet M and the wire passing from this to the working or primary channel 2^x when M is a magnet it attracts I
4324 depresses P and comes into good contact with L depresses
that end and raising the other out of contact with D, if the pillars be in connection with the battery as described and further shown by the figures 1. 2. 2^x in figure 6 it will be seen that while L rests upon D the current of electricity flows from the battery through 2, through E through L through D through the wire to the electro-magnet M round the magnet and away through the working channel back to the battery But while this is taking place M becomes a magnet, draws down I breaks contact between L and D and makes contact between P and L The electricity now flows from the battery through 2 to E through L to P and away through B and 1 to the battery. it will be clear that the current at D and L being broken the current cannot flow through the primary or working channel or round the electro-magnet which ceases to be a magnet and does not attract I The spring P flies up, contact between L and P is broken and contact is made as before between D and L and the same phenomenon again ensues The apparatus by which I cause a cessation or great diminution of electricity in the primary or working channel by means of giving the electricity a better and shorter channel than it would find in the primary one is as follows and is shewn in figure 7 A stand A has a pillar B of brass and spring C of brass with iron head I as before in figure 6 the pillar B is in connection with one pole of the battery and a pillar D of brass in connection with the other pole of the battery is fixed on the stand with its head under the spring C An electro-magnet M to which the iron I would form a keeper forms part of the main working or primary channel that is to say a wire in constant connection with one pole of the battery forms the coil of this magnet and is continued onwards to the apparatus which I call the main working apparatus and from thence back to the other pole of the battery and

is maintained in constant connection with it Now while the keeper I is up that is not drawn down by the attraction of M the electricity of the battery has but one channel to travel through videlicet the primary or working channel but if M draws down I so that E comes into contact with D and if the channel or circuit from the battery through B. C. D. and back to the battery is much shorter and far more easily traversed by the electricity than that of the primary or working channel then will the current of electricity forsake in a great measure the primary channel or circuit and flow in preference through the secondary channel B. C. D. for example suppose the resistance offered by the primary channel to the circulation of the electric current through it to equal one thousand, and suppose the resistance offered by the secondary channel to equal only ten then if both these channels were at one time fully in connection with
4325 the battery then would one thousand parts of electricity flow through the secondary or better conducting channel and only ten parts circulate through the primary or working channel which in effect would be practically to annihilate its effective power Thus to stop the action of the electricity in the working or primary channel I have only to offer to it an infinitely better secondary channel and the object is effected without breaking contact in primary channel and consequently no destructive spark is elicited Again when M has drawn C into contact with D and thus as described practically destroyed the current in the primary channel M ceases to have any attractive power as its coil forms part of the primary channel When this happens I is released and contact between C and D is broken the secondary channel is thus interrupted and the primary channel being still in good connection with the battery the electricity flows through it and does its work A very trifling and harmless spark is elicited at the head of D when contact is broken with C because the electricity has a free channel open to it through the primary channel and therefore does not follow C through any striking distance so as to be destructive The above descriptions and figure- 6 and figure 7 shew how contact is made and broken or the electric force annihilated or reduced in the primary channel by the agency of the electric current itself, but if it be desired to effect this at certain regular and defined intervals then the electro-magnets M M in figure- 6 and 7 are removed and levers or springs P C are brought into contact with D and D and removed from it by any convenient application of machinery to effect the motion at the proper intervals of time for example a cam wheel may rotate in front of the spring C and lift up the head I in the manner a cam wheel works a tilt hammer.

Another of the improvements forming part of my said invention consists in obtaining electric currents by causing a permanent magnet or combination of permanent magnets to rotate through a helix or helices of insulated wire If I use one magnet only for this purpose I make it of a circular form resembling a ring or hoop a portion of which has been cut out of it and between the ends or poles of the magnet I fix a piece of some non-magnetic body of the same breadth and thickness as the magnet so that with the

magnet it may form one continuous circle or ring I prefer however to use a combination of several magnets each of which I make in the form of a segment of a circle of the size which I intend the combination to assume when they are combined together and I make the magnets of such a size or sizes that when put together with pieces of non-magnetic material between their ends they shall form a circular hoop or ring of the intended dimensions
4326 Each of the segmental magnets just mentioned may be a
compound magnet that is to say may be composed of several magnets or magnetized steel plates placed one upon the other in the usual way I support a magnetic ring such as above described (whether composed of one or several magnets) upon the peripheries of three or more supporting or guiding wheels which I place within the interior of the magnetic ring as shewn in figures 8 and 9 These wheels I prefer to make with some soft or elastic material upon their peripheries so as to hold the ring more steadily during its rotation I mount the axes or spindles of these wheels in suitable bearings and I communicate motion to the ring either through the medium of one or more of these guide wheels or by means of a strap or belt applied to the exterior of the ring as shewn in figure 8 I cause a magnetic ring made in any of the ways above mentioned to rotate through the middle of one helix or several helices of insulated wire the interior or bore of each helix being made sufficiently large to permit the continuous rotation of the ring through it without touching the interior of it In figure 8 I have shewn an elevation or side view of a magnetic ring composed of two magnets supported upon three guide wheels rotating through a single helix of insulated wire and having motion given to it by means of a strap or belt applied to its periphery Figure 9 is an edge view of the same and in each of these figures similar parts are marked with similar letters of reference. A A and Z Z are the two magnets united together by two connecting pieces C C.—B B B are three guide or supporting wheels having flanges at their edges, and round the peripheries of which between the flanges are fixed coverings of vulcanized India rubber and the wheels are placed in such positions that they shall hold the ring securely in its proper position during its rotation D is the helix or coil made of insulated wire fixed upon the support G and with two projecting ends *x x* of the wire which may be connected with the connecting wires or other part of any apparatus in conjunction with which the machine is to be used F F is the strap or belt by means of which the ring is caused to rotate through the helix When a magnetic ring of any of the above descriptions is put together it must be introduced within each of the helices through which it will have to rotate before fixing the last segment or piece of the circle of which the ring shall be composed Although I have only shewn one helix or coil in these figures the magnetic ring may be caused to rotate through two or more such helices And if motion be given to the magnetic ring through the medium of one or more of the guide wheels in lieu of a strap or belt the ring may be made to rotate through a greater number of helices or coils I claim as this part of my in-

vention the obtaining of electric currents by causing such
4327 magnetic rings as aforesaid to rotate through a helix or
helices of insulated wire in manner aforesaid.

A farther part of my said invention consists in a mode of obtaining motion by the agency of electricity by means of a permanent or electro magnet fixed in one position and in front of the poles of this magnet a wheel rotates. On the periphery of this wheel are fixed small electro magnets in connection with a battery which on the revolution of the wheel pass close to the poles of the fixed magnet but do not touch them and the novelty of my invention consists in making these small electro-magnets neutral or feebly repulsive of the large fixed magnet immediately they come opposite to its pole.

Another part of my said invention consists in the use or application of wheels similar to an apparatus called Barlow's rotating wheel for producing motion For this purpose I mount several of such wheels upon the same spindle or axis causing each of them to work in a separate trough or reservoir of mercury or quicksilver I cause a current of electricity to pass successively through each of these wheels and in the same direction in each wheel that is to say from the centre to the periphery of each wheel or *vice versa* By the combined action of several of these wheels motive power may be communicated through the spindle on which they are fixed and the extent of the power will depend upon the number of wheels mounted on the spindle and the strength of the current of electricity employed

Another part of my said invention consists of the combined use or application of a plate or plates of lead as the positive plate or plates of a galvanic battery with a plate or plates composed of any metal which is electro-negative in relation to lead together also with a mixture of dilute nitric and sulphuric acid as the exciting fluid.

Another improvement forming part of my said invention consists in the combined use or application of tin as the positive plate or plates in a galvanic battery with a plate or plates composed of any metal which is electro-negative in relation to tin together also with a caustic alkaline solution as the exciting fluid.

Another improvement consists of a mode of obtaining electricity from a thermo-electric battery this improvement consists in the application of heat to the plates of the battery by means of a current or currents of dry air or any fluid which is not a good conductor of electricity The same effect may be produced by protecting the plates at the place or places where the heat is applied by any non-conducting body such as glass or varnish through which the heat may be conveyed to the plate or plates.

4328 My improvements in chemical decomposition by the aid of electric currents consists firstly in the use of a U tube in cases where it may be desirable that the products eliminated shall not be mixed The same effect may also be produced by a vessel divided into two parts by a partition which has an aperture therein from one division to the other below the surface of the liquid acted on The positive wire from this battery is to be introduced into one leg of the tube or compartment of the vessel and the negative wire into the other leg or compartment When it is desired to prevent the admixture of any gas evolved from a pole with the liquor under action I carry off such gas by putting a pipe open at each end over the pole mentioned and in the decomposition of bodies take chloride of sodium and reconvert it into other substance When it is desired to maintain the liberated chlorine or other matter as long as possible in contact with the liquor I cause the pole at which the chlorine or other matter is liberated to be sunk deeply into the liquid and I make the passage for the escape of the evolved gas &c. as long and as tortuous as possible

Another of my said improvements consists of a mode of purifying sugar in solution by the action of electric currents For this purpose I immerse two platina plates in connection with a galvanic battery in the solution of sugar to be purified and I pass currents of electricity through these plates and the solution in which they are placed for the purpose of causing the impurities contained in the sugar to be separable by filtration

In witness whereof I the said Martyn John Roberts have hereunto set my hand and seal this third day of January in the year of our Lord one thousand eight hundred and fifty three.

MARTYN JOHN (L. S.) ROBERTS.

Drew.

And be it remembered that on the third day of January in the year of our Lord 1853 the aforesaid Martyn John Roberts came before our said lady the Queen in her chancery and acknowledged the specification aforesaid and all and every thing therein contained and specified in form above written and also the specification aforesaid was stamped according to the tenor of the statute made for that purpose.

Enrolled the sixth day of January in the year of our Lord one thousand eight hundred and fifty three.

London: Printed for her majesty's stationery office, by Darling and Son.

4330*a* Def't's Exhibit Binks English Patent No. 119 of 1853.

No. 119.

Electric Lights.

Provisional specification left by Christopher Binks at the office of the commissioners of patents with his petition on the 18th January, 1853.

(Void by reason of notice to proceed not having been given within the time prescribed by the act.)

I, Christopher Binks, of Albert Villa, North Woolwich, in the county of Kent, do hereby declare the nature of the said invention for "improvements in producing electric light" to be as follows:

My invention relates to the forms, arrangements, and modes of working the electrodes and to the materials of which to construct the electrodes for producing light by electricity.

First part. In the ordinary arrangements of the carbon electrodes for producing light by a current of voltaic electricity two rods or pencils of solid charcoal are used, being placed end to end, and describing a straight vertical line, broken only at the point of juxtaposition of the two ends, between which is left a minute intervening space measuring ordinarily from about $\frac{1}{50}$th to $\frac{1}{4}$ of an inch, according to the strength of the passing current of electricity.
4330*b* These rods, though not in actual contact at their points of juxtaposition, form part of the circuit, connecting together the two poles of the battery, for the (so called) current of electricity passes through this intervening space, giving rise in its passage to the evolution of the electric light, but the quantity of light so evolved is in all such arrangements perpetually varying, for the quantity of light varies according to the distance one from the other of the carbon ends or points, and this distance is continually altering through possible alterations in the power of the battery, through the burning of the carbon, the disintegrating action upon it of the current of electricity, and the transference which takes place of particles of carbon from the one electrode to the other. The result is an intermittent light, the effects of a perpetual fluctuation in the amount evolved, which no contrivance hitherto applied with a view to the maintaining of the carbon points at a fixed distance under all the existing conditions of change has yet been able to obviate. Now, this first part of my invention consists in so constructing and arranging the electrodes that the unavoidable changes arising, as just described, in the material structure and in the relative distance of the electrodes are, in their inevitable effects upon the evolved quantity of light and upon the manner of its evolution, rendered either entirely impercept*a*ble or less percept-
4330*c* *a*ble than under the methods hitherto followed; whereby, consequently, by my invention a more uniform light or one less variable and intermittent is obtained; and my plan is

as follows: In place of forming each electrode (whether made of carbon or of other material) of a single rod or pencil (as heretofore) I form it of two, three, four, or more separate rods or pencils, and consequently have as many light-emanating points as there are separate rods; and these rods are placed close together and all act together as a common centre of emanation for the production of one light, so that the chances of perceptable variations in the amount and effects of the light evolved are reduced in proportion to the number of points into which the electrode is divided and that are brought into action at one time. This kind of arrangement I call the "compound electrode." A negative "compound electrode" may consist, for example, of two or three or four or more solid cylinders or rods of charcoal or other material placed side by side close together, but without actual contact, and having as many points (as there are rods) to be brought in juxtaposition (for the light-giving points) with the other or positive electrode, and the oppositive or positive electrode in this arrangement may consist of several cylinders or rods placed and acting side by side, or of only one cylinder or rod with its extremity
4330d brought into close juxtaposition with the ends or points of
the opposite compound electrode. The bundle or group of separate cylinders forming such a compound electrode may have one common connection with the battery or each cylinder may constitute an independent conductor. In all arrangements of light-giving electrodes where the material forming them is destructible under the action of electric current, as carbon is, one of them is more rapidly worn away than the other, and the one least acted on is called the "non-consuming" and the other "wasting" electrode. In the practical use of my invention of the several and various arrangements it is obviously capable of assuming, I prefer to employ a single rod of charcoal or other material for the non-consuming electrode and to place this undermost, and to use as the wasting electrode a combination of three separate rods connected by one common conductor to the battery. But I do not confine my invention to the use of this arrangement only; both electrodes may be "compound" and may be collectively connected with the battery or each of its rods may have an independent communication with the battery, and the "non-consuming" electrode may be a "compound" one, whilst the "wasting" electrode is made to consist of only a single rod, &c., &c. But, howsoever varied in detail, the nature of my invention is the same, namely, in place of one point of emination only, as hitherto, to have several points for each light. In an arrangement, for example, in which three rods of charcoal form a compound wasting electrode, should one of the three
4330e points become removed beyond the maximum light distance
by waste or transfer, &c., in quantity of the electricity that would otherwise pass through, this one point is thereupon transferred to the other two points still within full acting distance, and this transference serves immediately to increase the action, and, consequently, the quantity of light given out by these two or more active points. In the same way it results if two of the points be

thrown out of action fully or comparatively and only one remains in full activity, a more active current passes through this one remaining active point and the light it gives out increased in proportion. After the same manner it occurs when, in place of a "compound electrode" of three points, one consisting of four or five or of any other greater number is used. The wasting and shifting in distance of all the points in such compound electrodes can seldom if ever take place exactly to the same extent and at exactly the same moment of time, consequently a failure in any one point to give out light or its full quantity of light is comparatively unimportant, and those points least wasted or shifted compensate for or reduce the effects of such a deficiency to an extent that no contrivance, when applied to the old or single rod electrodes, has yet been able to secure.

I claim as my invention the forming of the electrode of two, three, or more rods or pencils or points of charcoal or other material instead only of one rod or pencil, as heretofore, or of so
4330*f* constructing the electrode that it shall have two, three, or
more light-em*i*nating points for each light in place of only one light-em*i*nating point, as heretofore.

The second part of my invention consists in using for the carbon electrodes the charcoal obtained by subjecting lignite to destructive distillation in close vessels—that is, I fully carbonize lignite and employ the hard close-grained charcoal thus obtained as the light-giving electrodes, for which it is admirably adapted and has not hitherto been used.

Third part. I form carbon electrodes by covering metal with a coating of carbon obtained by painting over the surface of the metal with tar or melted pitch or other like material or mixtures of any materials which on being strongly heated in close vessels yield a residue of solid carbon. Of such materials I prefer to use tar, pitch, bitumen, asphaltum, and rosin, or mixtures of finely pulverized charcoal or lamp-black with some adhesive vehicle which on being dried or strongly heated leaves a residue of solid or compact carbon. In this way I cover wires (platinum, copper, &c., &c.), narrow slips of metal rods, bars, plates, or other forms with carbon, leaving or not (at option) one portion of the metal uncovered, by which portion to connect the electrode with the battery. The portion coated with the carbon is that used as the electrodes proper, or parts
4330*g* brought in juxtaposition as the striking points for the pro-
duction of the light. By this means I obtain good conducting carbon electrodes, economise the power of the battery, and have power of electrodes more available than the fragile and imperfectly conducting long and thick rods or cylinders of carbon in use, or in place of coating metal in the manner above described I drill holes or cut grooves in solid pieces of charcoal for insertion of the wire or rod or other shaped metal intended to act as the conductor, or I affix thin slips or cuttings of charcoal or charcoal veneer by some adhesive material to the surfaces of slips, bars, plates, or other forms of metal to act as the conductor and to obtain improved forms and kinds of electrodes for production of the electric light.

I do not claim as my invention the use of carbon obtained by the destructive distillation of tar or of a mixture of such carbon and of lamp-black, for such carbon and mixture of carbon have long been known and used for electrodes, but I claim the use of lignite carbon for electrodes and the improved electrodes formed by coating or covering metal with carbon or charcoal as above described.

The fourth part of my invention consists in attaching one or both of the electrodes to a floating stem or stems, placed and working in some liquid (as water, mercury, oil, &c.) in order to obtain a 4330*h* simple and convenient power for moving the electrodes in order to maintain them at their proper relative distance or to replace them in their proper positions for producing the light when shifted out of it by the disintegrating action of the electric current on the charcoal, and for this purpose I balance the stem carrying the electrode in the liquid, so that as the carbon is burnt away the stem*s* becomes lighter and rises out of the liquid, and, in so doing, readjusts the distance or presents a fresh point or surface of carbon to the action of the opposite electrode.

Fifth part. In place of bringing (as heretofore generally done in such arrangements) the carbon electrodes together, end to end, in order to obtain the striking or light-em*i*nating points (as when two cylindrical rods are, as usual, brought in juxtaposition, end to end), I so form the electrodes that they can be placed and act concentrically, as, for example, a long cylindrical rod or pencil of charcoal placed and acting partly within a hollow cylinder or ring or truncated cone o*r* charcoal, the latter being a little longer in diameter than that necessary to merely admit the rod, so that the inner surface or edge at the end of the hollow cylinder or ring or cone will be close to but not in actual contact with the nearest portion of the side or exterior surface of the rod, and that the space between them at this point shall constitute the striking or light-em*i*nating point—that is, a narrow zone or belt on the exterior surface of 4330*i* the cylindrical rod at the point of it in closest juxtaposition with the inner edge of the end of the hollow cylinder or cone are the points through which the current of electricity passes and from which consequently the light is emitted. By any convenient mechanical contrivance the rod is made progressively to move within and through cylinder or cone through the entire length of the rod, in order to replace by a fresh surface that wasted from time to time by the action of the electric current. I prefer to make the hollow cylinder or cone the " non-consuming " electrode, and as the solid rod moves into and through it the fresh surface that is thus continually being presented by such movement is that which necessarily is the nearest to the opposite electrode, and through which consequently the current passes, and from which the light is obtained. The solid rods may be cylindrical or angular, being inserted in and moving through ap*p*ertures of corresponding shapes, so that the solid electrodes may be inserted and move within the other without actual contact. I vary this part of my invention when desirable by using " compound electrodes "—that is, in place, for example, of one solid charcoal rod moving within a solid cylinder I

employ two or more rods within one cylinder, or each of the two or more rods may be placed within its own corresponding hollow cylinder, but the two or more such sets are to be placed close
4330*j* together and act for the production of one light.

Again, in place of entirely encircling the rod of charcoal at the striking point on its exterior surface with the charcoal forming the opposite electrode, as above described, I make the latter to come in juxtaposition with only one side or face or part of the rod; as, for example, if the rod be a long, narrow slip of charcoal I cause another slip of charcoal to be placed close and parallel to it, but without actual contact, and the long slip to slide gradually past the other in a parallel direction so that the point of the side or face of the long slip that is nearest to the end of the shorter slip and the end of the shorter slip itself shall form the striking points, or I place the long slip between two other slips so that both sides or faces of it shall be in action, giving out light at the points nearest to the ends of the two other slips constituting together the opposite electrode.

I claim as my invention the using of carbon electrodes placed and acting concentrically or so that the end of one electrode and a point or points of the side nearest to it of the other electrode shall be the striking or light-em*i*nating points.

The sixth part of my invention consists in using the metal mercury for the electrodes in producing light, and for this purpose I employ two separate reservoirs of mercury, one connected with the positive and the other with the negative pole of the voltaic
4330*k* battery, and I cause the mercury from one reservoir to drop
into or upon the mercury in the other reservoir or a thin stream of metal to flow through a minute aperture from the one reservoir to the other, the quantity so flowing in a given time being so regulated in proportion to the quantity of current electricity in use that the stream of mercury at the point of contact or when in the act of coming into contact with the surface of the other mass of metal it falls into is partially or fully vaporized by the heat generated by the electric current, whereby a continuous and brilliant emission and light applicable to many important purposes is obtained. I vary this part of my invention by causing the drops or streams of mercury (in place of falling into the mass of mercury *in place of falling into the mass of mercury*) to fall upon charcoal or upon another metal or other conducting and light-giving material. With charcoal for one electrode and mercury for the other a combination is obtained which yields a most brilliant and valuable light. I confine the mercury so employed in a vessel or lamp so arranged that the vaporized portion of the metal is condensed, collected, and again applied to the same purpose.

I claim the use of mercurial electrodes for producing light by electricity and of one electrode formed of mercury and the other of carbon or of some other material for the same purpose and whether two electrodes or a greater number tha*t* two be used in such arrangements.

4330*l* The seventh part of my invention is as follows: I cause the light-giving electrodes of voltaic circuit intended to produce light successively to approach to (but without actual contact) and to recede from each other by such movement imparted to one or to both or to all the electrodes that the distance or the space between them shall — certain limits be continually changing and this so rapidly that the eye shall be unable to detect the different intensities of the light evolved under the different distances of the electrodes or when they are the nearest to and when the farthest apart from each other.

There is a certain point in the space between the electrodes in action in all such arrangements at which the maximum amount of light is obtained, but which point is not that of actual contact nor, perhaps, that the most immediately preceding actual contact, in the act of approaching to it. But this maximum-light point or the exact distance corresponding with it is the distance which inventors have hitherto attempted to secure and maintain by a fixture of the electrodes at it or by contrivances for replacing the electrodes in it when shifted by changes in the structure of the carbon through disintegration or transfer. But by my invention I do not fix or attempt to fix the distance of the electrodes at this point or to replace them in any fixed position when accidentally shifted from it
4330*m* or attempt (when the maximum-light point itself has shifted through any accidental change in the power of the battery) to make a corresponding shift for the time being of the position of the electrodes, but, on the contrary, I employ the conver*t* of all such methods—that is, I cause the electrodes (one or both *of* all of them, if there be more than two in the arrangement) to be continually changing their position and in doing so to travel thro' a certain space within the limits of which is embraced or lies the said maximum-light point, and the total or effective quantity or intensity of light that I do obtain is the mean of all the quantities evolved within this space, and the steadiness of the resulting light is due to the rapidity of the movement and in the capacity of the eye to detect the differences that really occur. In this way I obtain a light the quantity of which is the mean of the two extreme quantities obtained respectively when the electrodes are at the shortest and at the longest distance; and in consequence of the rapidity with which the changes in distance are made and by reason of a well-known law of vision the different quantities or degrees of intensity of the light are imperceptible, and consequently a steady or apparently uniform emanation of light or one free from any sudden fluctuation or fluctuations that are discern*a*ble *as* obtained. I obtain these changes in position or distance and the consequent results by impart-
4330*n* ing, by any convenient mechanical contrivance, a vibratory, an oscillating, a rotary, or other movement to one of the electrodes whilst the other remained stationary, or by such motion given to both the electrodes or to any set or number of electrodes, and I either employ a single arrangement of electrodes (that is, a single negative and a single positive electrode, constituting together

a set) as the source of the light, or I combine together for one light the effects of two or more sets of electrodes.

This peculiar movement or method of working the electrodes I obtain by the vibration of a wire or wires carrying the charcoal points, and which points, in the act of —, successively approach to — recede from each other within limits that may be adjusted and regulated according to the power of the current of electricity in use, or the movement can be given by the vibration of a metallic fork carrying the carbon on each branch, by an eccentric-wheel movement carrying the electrodes within the required limits rapidly towards and then away from each other on each revolution, by the revolution of two di-cs on a common axis, but revolving in contrary directions, carrying carbon arms or radiating on the electrodes and crossing each other scissorwise, but without actual contact at any time, and in this way causing the emanat-ry points or edges successively and continually to close upon and to separate from each other; by the rapid revolution of two carbon wheels with serrated 4330*o* edges placed and acting edge to edge, by the revolution of two wheels or rings placed concentrically with the proximate or light-emanating positions s*u*rrated or made angular, or the same general results may be obtained by a variety of other forms and arrangements of the electrodes, and the requisite motive power can be obtained by clock-work, by magneto-electric action, or otherwise; but, howsoever arranged or accomplished mechanically, I claim as my invention the causing the electrodes for producing light by electricity or the light-emanating points in a broken voltaic circuit alternately to approach to and to recede from each other by a movement imparted to one or both or to all the electrodes by any mechanical agency so that their distance shall be continually changing, but by so rapid a movement that the eye cannot detect the differences in the amount of light emitted that correspond with the difference in distance by which a light free from any sudden or apparently sudden fluctuations is produced.

(This method of producing a steady light I call the vibratory system to distinguish it from the others in this specification.)

The eighth part of my invention is as follows: When the two lights-giving electrodes in a voltaic circuit are brought into actual contact there is a point in the act of bringing them together at which the light is the most intense that 4330*p* the elements engaged are capable under any conditions of producing. It is a sudden flash of brilliant light; and this part of my invention consists in obtaining a steady light by causing those flashes to follow other in such rapid succession that the eye can distinguish no interval between them. By any convenient mechanism I bring the electrodes (whether two, as usual, or any other number) together and into actual contact, and again immediately separate them; and I repeat this making and breaking of contact a number of times in such rapid succession that an apparently uniform emission of light is obtained. I vary this part of my invention by giving to an arrangement of electrodes (whether consisting of two electrodes, as usual, or of several electrodes combined together for producing one light), yielding flashes of light by the successive and rapid making and breaking of contact between the opposite electrodes, a rotary motion by which the several independent flashes are blended together into an apparently uniform ring or disc or circlet of light (according to the form of the arrangement used), and in this way I obtain a steady light, or one free from any disagreeable or sudden fluctuations.

4330q The several arrangements of and contrivances for working the electrodes by causing them to vibrate or move between each other that are given under the seventh or immediately preceding part of my invention are applicable also to the carrying into practice of this the eighth part of my invention, with this difference only, namely, that whilst under the former or vibratory system the movement of the electrodes towards each other stop short of actual contact, in this (which I call the "blending" system) the contact is completed, though immediately broken again, on each vibration or movement of the electrodes.

I claim as my invention, in order to produce a steady or apparently non-intermittent electric light, by whatsoever mechanical contrivance it may be accomplished, the blending together of independent flashes of light emitted between two or more carbon or other electrodes on making and on breaking contact between them, by causing, by any convenient mechanical contrivance, such contact to be made and broken repeatedly in such rapid succession that no interval can be perceived between the flashes so produced; and I claim the blending together for one uniform light independent flashes of light obtained by making and breaking contact between the electrodes by causing the electrodes producing such flashes to rotate or move so rapidly as to blend the flashes together, and give the impression of an apparently uniform light.

Electric Lights.

Letters patent to John Thomas Way, of Welbeck street, in the county of Middlesex, for the invention of "improvements in obtaining light by electricity."

Sealed the 28th April, 1857, and dated the 29th October, 1856.

Provisional specification left by the said John Thomas Way at the office of the commissioner of patents with his petition on the 29th October, 1856.

I, John Thomas Way, of Welbeck street, in the county of Middlesex, do hereby declare the nature of the invention for "improvements in obtaining light by electricity" to be as follows:

Heretofore in obtaining light by means of electricity electrodes a set) as the source of the light, or I combine together for one light the effects of two or more sets of electrodes.

This peculiar movement or method of working the electrodes I obtain by the vibration of a wire or wires carrying the charcoal points, and which points, in the act of —, successively approach to — recede from each other within limits that may be adjusted and regulated according to the power of the current of electricity in use, or the movement can be given by the vibration of a metallic fork carrying the carbon on each branch, by an eccentric-wheel movement carrying the electrodes within the required limits rapidly towards and then away from each other on each revolution, by the revolution of two di-cs on a common axis, but revolving in contrary directions, carrying carbon arms or radiating on the electrodes and crossing each other scissorwise, but without actual contact at any time, and in this way causing the emanat-ry points or edges successively and continually to close upon and to separate from each other; by the rapid revolution of two carbon wheels with serrated
4330*o* edges placed and acting edge to edge, by the revolution of
two wheels or rings placed concentrically with the proximate or light-emanating positions s*u*rrated or made angular, or the same general results may be obtained by a variety of other forms and arrangements of the electrodes, and the requisite motive power can be obtained by clock-work, by magneto-electric action, or otherwise; but, howsoever arranged or accomplished mechanically, I claim as my invention the causing the electrodes for producing light by electricity or the light-emanating points in a broken voltaic circuit alternately to approach to and to recede from each other by a movement imparted to one or both or to all the electrodes by any mechanical agency so that their distance shall be continually changing, but by so rapid a movement that the eye cannot detect the differences in the amount of light emitted that correspond with the difference in distance by which a light free from any sudden or apparently sudden fluctuations is produced.

(This method of producing a steady light I call the vibratory system to distinguish it from the others in this specification.)

The eighth part of my invention is as follows: When the two light*s*-giving electrodes in a voltaic circuit are brought into actual contact there is a point in the act of bringing them together at which the light is the most intense that
4330*p* the elements engaged are capable under any condi-
tions of producing. It is a sudden flash of brilliant light; and this part of my invention consists in obtaining a steady light by causing those flashes to follow other in such rapid succession that the eye can distinguish no interval between them. By any convenient mechanism I bring the electrodes (whether two, as usual, or any other number) together and into actual contact, and again immediately separate them; and I repeat this making and breaking of contact a number of times in such rapid succession that an apparently uniform emission of light is obtained. I vary this part of my invention by giving to an arrangement of electrodes (whether consisting of two electrodes, as usual, or of

several electrodes combined together for producing one light), yielding flashes of light by the successive and rapid making and breaking of contact between the opposite electrodes, a rotary motion by which the several independent flashes are blended together into an apparently uniform ring or disc or circlet of light (according to the form of the arrangement used), and in this way I obtain a steady light, or one free from any disagreeable or sudden fluctuations.

4330*q* The several arrangements of and contrivances for working the electrodes by causing them to vibrate or move between each other that are given under the seventh or immediately preceding part of my invention are applicable also to the carrying into practice of this the eighth part of my invention, with this difference only, namely, that whilst under the former or vibratory system the movement of the electrodes towards each other stop short of actual contact, in this (which I call the "blending" system) the contact is completed, though immediately broken again, on each vibration or movement of the electrodes.

I claim as my invention, in order to produce a steady or apparently non-intermittent electric light, by whatsoever mechanical contrivance it may be accomplished, the blending together of independent flashes of light emitted between two or more carbon or other electrodes on making and on breaking contact between them, by causing, by any convenient mechanical contrivance, such contact to be made and broken repeatedly in such rapid succession that no interval can be perceived between the flashes so produced; and I claim the blending together for one uniform light independent flashes of light obtained by making and breaking contact between the electrodes by causing the electrodes producing such flashes to rotate or move so rapidly as to blend the flashes together, and give the impression of an apparently uniform light.

A. D. 1856. No. 2547.

Electric Lights.

Letters patent to John Thomas Way, of Welbeck street, in the county of Middlesex, for the invention of "improvements in obtaining light by electricity."

Sealed the 28th April, 1857, and dated the 29th October, 1856.

Provisional specification left by the said John Thomas Way at the office of the commissioner of patents with his petition on the 29th October, 1856.

I, John Thomas Way, of Welbeck street, in the county of Middlesex, do hereby declare the nature of the invention for "improvements in obtaining light by electricity" to be as follows:

Heretofore in obtaining light by means of electricity electrodes of charcoal have usually been employed, and motion has commonly been given to such electrodes by clock-work or otherwise, so as constantly to change their acting points; but even with this precaution it has been very difficult to obtain a constant light, in consequence of the want of uniformity in the electrodes. Now, this invention consists in the use for one of the electrodes of a substance such as mercury, which is caused to flow through an orifice or orifices on to a point or points of steel or other material. The mercury 4330s is in connection with one of the poles of the battery, and the points are in connection with the other pole of the battery, and they are so arranged that the distance between them and the orifices from which the mercury escapes can be adjusted so as to bring the points to the level, at which the streams of mercury break into drops. In place of using points of steel or other material for the lower electrode, a regulated surface of mercury may be employed, if desired, and the apparatus may be surrounded by a glass to prevent the escape of mercurial fumes; means also may be provided for raising the mercury from the lower receiver into which it falls from the orifices to the upper receiver or cistern which supplies the jets.

Specification in pursuance of the conditions of the letters patent filed by the said John Thomas Way in the Great Seal Patent Office on the 29th April, 1857.

To all to whom these presents shall come I, John Thomas Way, of Welbeck street, in the county of Middlesex, send greeting:

Whereas her most excellent majesty Queen Victoria, by her letters patent bearing date the 29th day of October, in the year of our Lord one thousand eight hundred and fifty-six, in the twentieth year of her reign, did, for herself, her heirs and successors, give and grant unto me, the said John Thomas Way, her special li- 4330t cense, that I, the said John Thomas Way, my executors, administrators, and assigns, or such others as I, the said John Thomas Way, my executors, administrators, and assigns, should at any time agree with, and no others, from time to time and at all times thereafter during the term therein expressed should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel islands, and Isle of Man an invention for "improvements in obtaining light by electricity" upon the condition (amongst others) that I, the said John Thomas Way, my executors or administrators, by an instrument in writing under my or their or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent:

Now, know ye that I, the said John Thomas Way, do hereby declare the nature of the invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement thereof—that is to say:

Heretofore in obtaining light by electricity electrodes of charcoal
have usually been employed, and motion has commonly been
4331 given to such electrodes by clock-work or otherwise, so as
constantly to change their acting points, but even with this
precaution it has been very difficult to obtain a constant light in
consequence of the want of uniformity in the electrodes.

Now, this invention consists in the use for one of the electrodes of a substance such as mercury, which is caused to flow through an orifice or orifices onto a point or points of steel or other material. The mercury is in connection with one of the poles of the battery, and the points are in connection with the other pole of the battery, and they are so arranged that the distance between them and the orifices from which the mercury escapes can be adjusted so as to bring the points to the level at which the streams of mercury break into drops. In place of using points of steel or other material for the lower electrode a regulated surface of mercury may be employed if desired, and the apparatus may be surrounded by a glass to prevent the escape of mercurial fumes; means also may be provided for raising the mercury from the lower receiver, into which it falls from the orifices, to the upper receiver or cistern which supplies the jets.

Having thus stated the nature of my said invention, I will proceed more fully to describe the manner of performing the same:

I use a cistern of iron, slate, or other suitable material, in which
the mercury is led by a pipe (with a stop-cock) to a jet, with
4332 as small an orifice as I can conveniently make, from which
by its own weight the mercury will flow in a constant
stream. I find a height of from two to four feet to give a suitable pressure, but I do not confine myself to a particular pressure. It is obvious also that the jet or jets may be thrown upwards or in any other direction that may be desirable, but I prefer that it should descend from the orifice by gravity. The necessary pressure may be obtained by mechanical means. When a small power only is employed the mercury may descend onto a point of steel, platinum, charcoal, or other conductor in connection with one pole of the battery, the mercury itself being connected with the other pole, and it is important that the second electrode (or one of the electrodes) should be capable of ready adjustment to insure its being at the point where the stream of mercury breaks in order that there may be a space between the stream and the second electrode. When the electric power is great I find that a point electrode is liable to be destroyed, and in such cases I employ a small cup of mercury made of infusible material, such as fire-clay or other matter, so arranged that the mercury therein shall be in connection with one pole of the battery, and I find that it is desirable that the mercury should flow off only on one side from the small cup, for which reason I make
the cup cylindrical and about half an inch in diameter, with
4333 the upper edge higher on one side than the other, so that the
edge is formed to an inclination or angle of forty-five de-

grees. The use of a small cup of mercury for the second electrode is important, as on the one hand it does not materially interfere with the light passing downwards, and at the same the quantity of mercury subject to the heat is small as compared with the quantity which would be present if the mass of mercury formed the second electrode. The mercury flows away by a pipe from below the small cup into any convenient re*ci*ptacle, from which it may be returned by hand, by a pump, or other means to the upper cistern. Finally, a glass is used to retain the fumes of mercury. The glass is cemented into the two cast-iron cylinders which form the upper and lower parts of the apparatus. This glass is to be as infusible as may be, and its size may vary from an inch in diameter to two inches or more, according to the size of the light to be produced. Instead of being a cylinder the glass may be fixed in segments in a frame of metal, but in that case means must be taken to isolate one or other of the electrodes. Whether a metal or other conducting point or a cup of mercury be used it is essential that means should be employed to adjust the distance between the two electrodes. For this purpose a screw or rack and pinion or other equivalent mechanism is to be used in combination with one or other of the electrodes in order that the distance apart of the electrodes may be regulated thereby, and that they may be retained at a distance apart corresponding with the breaking point of the stream of mercury. 4334

I would remark that I am aware that it is not new to employ a stream of mercury as an electrode in apparatus for obtaining light by electricity. I do not, therefore, claim the same, neither do I claim the adjusting of an electrode by a screw or other mechanical apparatus when separately considered; but what I claim is the use of a flowing electrode of mercury in combination with apparatus for regulating the distance apart of the two electrodes, and I also claim the combination of a small overflowing cup or regulated surface of mercury as a second electrode with a flowing electrode of mercury in apparatus for obtaining light by electricity.

In witness whereof I, the said John Thomas Way, have hereunto set my hand and seal this twenty-seventh day of April, in the year of our Lord one thousand eight hundred and fifty-seven.

JOHN THOMAS WAY. [L. S.]

Witness:

Electric Light.

Letters patent to Charles Weightman Harrison, of Woolwich, in the county of Kent, civil engineer, for the invention of "improvements in obtaining light by electricity."

Sealed the 28th August, 1857, and dated the 28th February, 1857.

Provisional specification left by the said Charles Weightman Harrison at the office of the commissioners of Patents with his peti tion on the 28th February, 1857.

I Charles Weightman Harrison of Woolwich in the county of Kent, civil engineer, do hereby declare the nature of the said invention for "improvements in obtaining light by electricity," to be as follows:—

My invention relates firstly to the preparation of electrodes.

It is well known that condensed gas carbon from its great purity and density is the best and most durable form of charcoal for the display of electric light.

Now one of my improvements under this head of my invention consists in placing pieces of metal or other material in gas retorts or in tubes connected therewith, for the purpose of receiving a deposit of gas carbon. I allow the pieces to remain exposed to the action of the gas until they are coated to a desired thickness and I then cut or grind them down to any required form of electrode.

4337 Another of my improvements under this head of my invention consists in the use of electrodes of spongy or powdered metals prepared by means of compression into any determinate shape or cut to a required form from blocks or masses of such compressed metals. In the employment of these electrodes I produce lights of various colors according to the kind of metal or combinations of metals used.

My invention relates secondly to an arrangement of electrodes.

In every apparatus employed up to the present time it is necessary in order to obtain a continuous light that the electrodes should approach each other as fast as diminution takes place, but by my improvements this necessity is obviated. I employ a cylindrical electrode and placing it on an axis in the direction of its length, I impart to it by suitable arrangements, a rotary as well as horizontal or onward motion in the line of its axis. Opposite to the periphery or circumference of this electrode I place another electrode and by preference I use one that is in the form of a point or pencil, the apex being in contact with the circumference of the cylindrical electrode and near to one of its ends. If motion be now given as herein-before stated to the cylindrical electrode, the opposide electrode will trace a spiral path over its surface from one end to the other, the contiguity of the convolutions being determined by the rate of its onward progression. In order to obtain the light I connect the opposite or pointed electrode with the armature of an electro-magnet or with a coil of conducting medium in such manner that on the transmission of a current of electricity this electrode is drawn or moved away to a suitable distance from the other and then retains a fixed position until on breaking the electric circuit it again renews the contact. I form the circuit of the current so as to render the rotary cylinder an electrode of positive electricity, and the point or pencil an electrode of negative electricity. The light being by these arrangements produced on the circumference of the cylindrical electrode and its motion continuously bringing fresh surface to the operation of the luminous portion of the current, an uniform amount of resistance is offered to its passage and the light is generated with a steady constancy due to that of the current itself.

The third part of my invention relates to a mode of maintaining a very uniform distance between a rotary disc positive electrode and a point or pencil negative electrode. The said mode consisting principally in keeping in contact with the periphery of a rotary disc electrode a roller or pulley or other contrivance which is connected by a chain or band or by levers with a pendant or sliding point or pencil electrode, whereby as the positive electrode diminishes the negative electrode is permitted continuously to advance without causing sudden fluctuations in the light.

4338 The fourth part of my invention refers to improvements in producing a succession of flashes or streams of light.

It has already been proposed to obtain electric light by a rapid succession of flashes resulting from the vibration, produced by mechanical agency, of electrodes. I do not therefore claim as new that which has been done before but I adopt the use of one or more electro-magnets to give rise to or effect a reciprocative or vibrative motion in electrodes. I sometimes employ a steel armature in connection with the electro-magnets so that its residual magnetism shall serve to retain the electrode or electrodes in the position assumed during the passage of the last current. On the arrival of each succeeding current, the transmission of which is regulated by a suitable electrotome, the electrodes are moved away one from another by the force originated by the current, a flash or stream of light is produced and the residual magnetism holds the electrodes in position for another electric impulse.

Another mode whereby I produce successive flashes or streams of light consists in the employment of a coil of conducting medium, and by means of an axial bar or magnet used in connection therewith a vibratory motion is given on the passage of the current to one or more electrodes. In those arrangements of electrodes where contact is made between them I prefer to introduce therein a spring or some compressible body in such a manner and position that it will break the force of concussion. In any arrangement of a vibratory system of electrodes I employ an electrotome by which the current is so directed that it shall at every impulse impart a negative nature to the vibrating electrode.

This part of my invention is very suitable for lighting marine buoys, the electricity being conveyed through insulated submarine conducting medium.

The fifth part of my invention relates to the introduction of an inductive coil (formed either with or without a condensing arrangement) to be used in connection with a primary current, and one of my improvements herein consists in given any required motion to electrodes by the operation of the primary current and producing light by means of the induced current alone.

The sixth part of my invention consists in combining the current generated in an inductive coil with a current of magneto-electricity produced by the motion of a conductor within the action of permanent magnets.

The seventh part of my invention consists in a peculiar mode of obtaining the electric light by which signals are effected. It comprises the application and use of an electrotome or an arrangement of electrotomes by which the current shall be let on both at
4339 rapid and at long intervals, or both at rapid, at short and at
long intervals. At each passage of the current a distinct flash of light is produced and this may be taken to denote an unit, the short intervals the end of a number and the long intervals to signify either the termination of the signals, as when a repetition of it is desired, or the end of a combination of numbers. This system may be made to represent words or sentences as well as numerals and being easily understood it is well adapted to lighthouses.

I also propose to indicate to vessels by flashes of electric light the depth of water in harbours or on banks, and to effect this by means of a float within a tube, which, by suitable mechanical contrivances, as it rises and falls calls into operation different electrotomes and these by completing the circuit of the current give rise to flashes of light, in number according to the depth of water in feet. To distinguish this from other marine lights I make it a colored light by placing a colored glass before it, or by the use of my improved metal electrodes described in the first part of this my provisional specification.

Specification in pursuance of the conditions of the letters patent filed by the said Charles Weightman Harrison in the Great Seal Patent Office on the 28th August, 1857.

To all to whom these presents shall come I, Charles Weightman Harrison, of Woolwich, in the county of Kent, civil engineer, send greeting:

Whereas her most excellent majesty Queen Victoria by her letters patent bearing date the twenty-eighth day of February in the year of our Lord one thousand eight hundred and fifty-seven in the twentieth year of her reign did for herself her heirs and successors give and grant unto me the said Charles Weightman Harrison her special licence that I the said Charles Weightman Harrison my executors administrators and assigns or such others as I the said Charles Weightman Harrison my executors administrators and assigns should at any time agree with and no others from time to time and at all times thereafter during the term therein expressed should and lawfully might make use exercise and vend, within the United Kingdom of Great Britain and Ireland the Channel islands and Isle of Man an invention for "improvements in obtaining light by electricity" upon the condition (amongst others) that I the said Charles Weightman Harrison my executors or administrators by an instrument in writing under my or their or one of their
4340 hands and seals should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent.

Now know ye, that I the said Charles Weightman Harrison do hereby declare the nature of my said invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement thereof reference being had to the accompanying drawings and to the figures and letters marked thereon that is to say,

My said invention relates firstly to the preparation of electrodes for producing light.

It is well known that condensed gas carbon from its great purity and density is the best and most durable form of charcoal for the display of electric light.

Now one of my improvements under this head of my invention consists in placing pieces of metal or other material in gas retorts, or in tubes connected therewith for the purpose of receiving a deposit of gas carbon. I form hollow cylinders of carbon or barrel electrodes by passing a current of coal gas through a chamber which is traversed by metal tubes joined with a furnace the flame and heated air of which are drawn through the tubes. When these attain a red heat they gradually become coated with a dense form of carbon. I form pencil or solid carbon electrodes by suspending small rods or pencils of wood charcoal upon a frame of iron, which I place within a heated gas chamber or retort, where it will be subjected to a high degree of heat. By this process the charcoal is rendered hard and lasting. I allow the tubes and pieces to remain exposed to the action of the gas until they are coated to a desired thickness and I then cut or grind them down to any required form of electrode.

Another of my improvements under this head of my invention consists in the use of electrodes of spongy or powdered metals prepared by means of compression into any determinate shape or cut to a required form from blocks or masses of such compressed metals. I first slightly moisten the metallic powder and having placed it in an iron mould of any suitable shape, I apply hydraulic or other pressure to a piston which accurately fits the aperture of the mould. In this way the pulverulent matter is solidified and made suitable for use in electric light apparatus. In the employment of these electrodes I produce lights of various colors according to the kind of metal or combination of metals used. The metallic dust 4341 may be mixed in various proportions with carbon or other substance. I obtain a brilliant white light by using a positive electrode formed of a combination of zinc powder and plumbago and consisting of three parts of plumbago with one of zinc.

My invention relates secondly to an arrangement of electrodes.

In every electric light apparatus employed up to the present time it is necessary in order to obtain a continuous light that the electrodes should approach each other as fast as diminution takes place, but by my improvements this necessity is obviated. I employ a cylindrical electrode and placing it on an axis in the direction of its length. I impart to it by suitable arrangements a rotary as well as horizontal or onward motion in the line of its axis. Opposite to the periphery or circumference of this electrode I place another electrode and by preference I use one that is in the form of a point or pencil the apex being in contact with the circumference of the cylindrical electrode and near to one of its ends. If motion be now given as herein-before stated to the cylindrical electrode the opposite electrode will trace a spiral path over its surface from one end to the other, the contiguity of the convolutions being determined by the rate of its onward progression. In order to obtain the light I connect the opposite or pointed electrode with the armature of an electro-magnet or with a coil of conducting medium in such a manner that on the transmission of a current of electricity this electrode is drawn or moved away to a suitable distance from the other and then retains a fixed position until on breaking the electric circuit it again renews the contact. I form the circuit of the current so as to render the rotary cylinder an electrode of positive electricity, and the point or pencil an electrode of negative electricity. The light being by these arrangements produced on the circumference of the cylindrical electrode, and its motion continuously bringing fresh surface to the operation of the luminous portion of the current an uniform amount of resistance is offered to its passage, and the light is generated with a steady constancy due to that of the current itself. To obtain the maximum amount of light it is necessary to proportion the distance between the electrodes to the intensity of the electricity employed. I provide means for effecting this object by placing the electro-magnet or its armature on a movable support which will admit of the distance between them being increased or diminished at pleasure. The duration of the light will of course depend upon the size of the rotary barrel electrode and as by its motion which is derived from clockwork or other suitable means it maintains a steady and permanent light I have in contradistinction to other electric lights called this arrangement the electric constant light apparatus.

In order that this part of my invention should be fully as-
4342 certained and in what manner it may be performed I will
now proceed to describe and refer to the several figures on the first sheet of drawings hereunto annexed.

Figure 1 is a front elevation of one of my electric light apparatuses complete. Figure 2 is a side elevation of the same, parts being removed to shew the interior. Figure 3 is a plan of apparatus fixed on a base board. In each of these figures the same letters refer to like parts.

a is a hollow cylinder or barrel positive electrode of which a cross section is shewn in figure 13. *b* is the central rotary axis shewn separate in figure 7. *c* is a fixed hollow screw within which the central axis works shewn detached in figures 8 and 9. *d d* are clamp circular plates or discs having an interior rim fitting the aperture in the barrel electrode, one of the plates is fixed on the end of a hollow axis, the other end being formed with a screw, by which to connect the second plate and thus clamp or hold the electrode in position these are shewn separately in figures 10 and 11. Within this hollow axis the fixed hollow screw containing the central axis is placed. One end of the central axis carries a pulley which is connected by the chain or cord *e* with the driving pulley *f* actuated by clockwork apparatus held by the frame *g g* *h h* are hollow standards supporting the barrel electrode *i* is the negative electrode held by the pendant socket *j* in which is a projection fitting in a recess or groove *k* in the electrode to prevent its falling out. For the purpose of affording a convenient means of fixing the electrode, the socket is made to open in two parts, one of which is removed in this figure but they are shewn together in figures 5 and 6. *l* is part of the mouthpiece of the standard *m*; the other part being fixed on the slide or door which is here removed. To facilitate the passage of the current I line the inside of the mouthpiece with platinum. The negative electrode passes freely through this mouthpiece without lateral deviation when drawn upwards. *n* is a cord carried over the pullies *o o* one end being hooked to a ring in the socket and the other end to the bar *p* *q* is an electro-magnet fixed by the bracket *r* to the plate *s* which moves on another or bed plate *t*, secured on the block or bridge of wood t^1 *u* is a screw working through the bracket *r* and employed to adjust the distance apart of the magnet *q* and armature *w* this armature is attached to a short arm *x* of the lever *y* which is supported on the axis *z*. The long arm of the lever passes under the bed plate *t*, and terminates in a forked end; to this fork a pair of spring nippers a^1 a^1 is attached and these are so regulated by the screws b^1 b^1 working in the

bracket c^1 c^1 that at the moment the armature is attracted by the electro-magnet they take hold of the bar *p*, fixed to the end of the chain, and carry it down with the lever d^1 is a bent rod fixed to the
armature which as it is drawn to the magnet causes the rod
4343 to depress a short ivory stud secured on the end of the axis
e^1 carrying an arm furnished with a pin at the end that drops in between the teeth of the wheel f^1 and thus stop the motion of the clockwork when the current is cut off g^1 is an adjustment acting on a balance wheel for the purpose of varying the rate of motion h^1 is a spring regulated by a screw and serving to withdraw the armature from the magnet on the occurrence of a break or loss of power in the current k^1 k^1 k^1 k^1 are screws to fasten down the base board l^1 to the bottom of the case m^1.

Still further to make plain the connection and general operation of the several parts of the apparatus I shall now state the direction traversed by the current. The screw P being brought into contact with a conductor from the positive pole to the screw N with another conductor from the negative pole of a voltaic battery or other suitable source of electricity, the circuit will be from N to the standard *h* thence through the central axis and screw clamp plate to the rotary barrel electrode. From this it passes to the opposite point or pencil electrode and it is in so doing that the great resistance to the passage of the current gives rise to heat and light the amount of which is proportionate to the power of the current and to the nature of the electrodes. From the pencil electrode the circuit is through the mouthpiece *l* and socket *j* down the standard *m* to a wire by which it is carried around the electro-magnet to the screw P.

Of the remaining figures in the first sheet of drawings figure 4 represents a back elevation of the mechanism by which the negative electrode is withdrawn *n* is a cord attached to the socket *j* *p* is a bar a^1 a^1 are spring nippers fixed on the fork of lever *y* *y* b^1 b^1 adjusting screws working through brackets fixed to the under side of case *m*. Figure 5 is a front view of socket figure 6 cross section of the same *a* the part which opens or may be detached *b* aperture to contain electrode and *n* the chain or cord. Figure 7 central axis which for the purpose of giving a rotary motion to the electrode is made flat on one side for half of its length the hole in the screw clamp plate being made of a similar form to receive it; *a*, chain pulley. Figure 8 hollow screw to contain central axis, one end terminates in a shoulder plate by which it is fixed in a recess formed in its bearing standard. Figure 9 is an end view of this shoulder plate, *a* being the aperture in which the central axis revolves. Figure 10 shews the hollow clamp axis; an end view of the fixed clamp plate is shewn in figure 11. *a*, clip or tongue which being held by the pressure of the spring *b*, between the thread of the screw carries the electrode as it revolves along the line of its axis. *c* loose clamp
plate screwing on to the end of the hollow axis when passed
4344 through the electrode. Figure 12 is a front view of a barrel
screw electrode, the apex of the thread when in motion in the apparatus being continuously brought under the point of another electrode placed at right angles to it. Figure 13 is a cross section

of a barrel electrode *a*, tube of iron *b*, deposit of gas or other carbon.

The third part of my invention relates to a mode of maintaining a very uniform distance between a rotary disc positive electrode and a point or pencil negative electrode, this mode consists principally in keeping in contact with the periphery of a rotary disc electrode a roller or pulley or other contrivance which is connected by a chain or band or by levers with a pendant or sliding point or pencil electrode, whereby as the positive electrode diminishes, the negative electrode is permitted continuously to advance without causing sudden fluctuations in the light.

The manner in which this part of my invention may be carried into effect will be understood by reference to the figures in the second sheet of the accompanying drawings and to the following description.

Figure 1 is a front elevation of the complete apparatus and figure 2 is a side elevation, part of the case and of one of the standards supporting the disc electrode being removed to shew the mechanism. *a* positive disc electrode to which a rotary motion is imparted by a pulley fixed on one end of its axis being connected with another pulley driven by clockwork held in the frame *b*—*c* negative electrode fixed in a socket sliding in the standard *d* where it is held pendant by the cord *e* passing over pulleys placed therein—*f* sliding frame carrying a pulley around which the cord is conveyed—*g* spring nippers attached to the lever *h*—*i* screws for regulating the pressure of the nippers on the sliding frame—*j* axis of lever—*k* armature borne on the end of the adjusting screw *l* which passes through the short elbow of the lever—*m* is an electro-magnet supported on the bed *n*, and held by the bracket *o*—*p* pulley over which the cord is conveyed and made fast to a cross pin at the lower end of the sliding frame *q*—*r* is a pulley fixed in this frame and held against the disc electrode by the weight of the pendant socket and negative electrode—*s s* are hollow standards supporting the disc.

Upon connecting the binding screws P and N with a suitable voltaic battery, the electricity will pass from N around the electromagnet, and up a standard *s* to the disc electrode on the periphery of which the light is produced. Through the negative electrode the electricity is carried to the standard *s* and thence to the second binding screw P—The action of the apparatus is as follows—upon the soft iron or armature at one end of the lever being attracted by the electro-magnet, the nippers attached to the other end of the lever are drawn down carrying with them the pulley frame
4345 through which the cord connected with the negative electrode
is passed the extent of this movement is restrained by an adjusting screw. As the rotary positive disc is consumed the pulley in contact with its edge will be raised thereby lowering in exact proportion the other electrode. Upon the current ceasing to pass, the nippers liberate the frame, and the negative electrode rests upon the disc ready for further use.

The fourth part of my invention refers to improvements in producing a succession of flashes or streams of light.

It has already been proposed to obtain electric light by a rapid succession of flashes resulting from the vibration produced by mechanical agency of electrodes. I do not therefore intend to claim as new the obtaining of electric light by a succession of flashes. I employ however for the purpose one or more electro-magnets to give rise to or effect a reciprocative or vibrative motion in electrodes and prefer to use the metal mercury for the positive electrode in producing flashes or streams of light.

In sheet 3 of the annexed drawings, figure 1 is a plan and figure 2 a side elevation partly in section of an arrangement by which this part of my invention may be carried out, as a lamp suitable for vessels at sea, or locomotives on land, there being no liability to the light ceasing, and as the flashes of light are produced with exceeding rapidity they appear almost as one sparkling light—*a*, is a frame or case provided with suitable slides or doors for gaining access to the interior—*b* lens—*c* bent glass vessel having a close fitting lid *s*, at the elbow—*d*, *d*, sockets or hollow pistons working through the lid *s*, and connected by short rods with the beams *f*, *f*, supported on the standards *g g*—*h h*, rods which unite the short end of each beam with the balance *i* working on the axis *j*,—*k*, *k*, are adjusting screws passing through the balance and holding the soft iron armatures *l*, *l*. m, m^1 are electro-magnets—*n* is a reservoir or supply vessel with an opening *u* at the top to admit the open end of the glass vessel *c*, and also connected near the bottom with the glass vessel by a small tube or pipe *p*—*t* is a reflector—*e*, *e*, are two hollow pencil negative electrodes securely fastened in their sockets—*s* is an aperture to admit mercury into the reservoir—the various parts of the apparatus are securely fixed to the base board *q*, which slides within the lamp and is held down by the screws *r*, *r*. The path of the current is from the binding screw N fixed in the iron reservoir containing the supply of mercury which forms the positive electrode in the glass *c*, thence alternately through each of the negative electrodes e, e^1 and around its electro-magnet to the binding screw P. In this way the lamp continues in operation, as the electro-magnets are excited they successively attract their armature which drawing down the 4346 balance connected to the beams raises a negative electrode from the mercury and produces a flash of light. At the same time the short end of the other lever being raised by the balance causes the other negative electrode in its turn to complete and then break the circuit and thus give another flash of light. As mercury when used for the positive electrode in the production of light undergoes a rapid evaporation, I provide means, by carrying the bent glass vessel over into the supply reservoir for its condensation therein, and to facilitate this I sometimes cover the mercury therein with water. I find it of great advantage to employ hollow negative electrodes in connection with a positive electrode of mercury.

I sometimes employ steel armatures in connection with the electro-magnet in place of soft iron, so that its residual magnetism shall serve to retain the electrode or electrodes in the position assumed during the passage of the last current. On the arrival of each succeeding current the transmission of which is regulated by a suitable electrotome, the electrodes are moved or drawn away one from another by the force originated by the current, a flash or stream of light is produced, and the residual magnetism holds the electrodes in position for another electric impulse.

Another mode whereby I produce successive flashes or streams of light consists in the employment of a coil of conducting medium and by means of an axial bar or magnet used in connection therewith a vibratory motion is given on the passage of the current to one or more electrodes which may be arranged as herein last before described. In any arrangement of a vibratory system of electrodes, I so direct the current that it shall at every impulse impart a negative nature to the vibrating electrode.

This part of my invention is very suitable for lighting marine buoys the electricity being conveyed through insulated submarine conducting medium. Figure 3 in sheet 3 of the drawings represents the plan of an arrangement by which I propose to light up any number of marine buoys or beacons one after another successively by the same electric current; the buoys being moored around shoals or sand beds, as for instance the Goodwin, would by the continuous running of the light completely surround them with a belt of fire and thus afford a valuable means of preventing shipwreck—*a* is a submarine electric cable, communicating through a flow and return insulated conductor with the light producing electrodes placed under a strong bell glass or frame on each buoy. The two ends of the submarine cable are placed in connection with an electrotome formed as shewn in the figure. One end of each insulated conductor is joined to a binding screw numbered in the figure similar to the buoy it is in communication with, and this by means
4347 of a spring a^1 forms contact with a projecting tooth of the barrel *b*, the axis of this barrel carries a toothed wheel *c*, which is drawn round a distance of one tooth by a claw in the end of the arm *d*, each time that the armature *h*, is released from the electro-magnet—*e* is the lever borne on an upright axis *f*, and connected, one end with the upright *g*, working on an axis and carrying the armature, the other end is joined to the arm *d*,—*i* is a spring regulated by a screw and pressing back the armature when the current is broken—N binding screw from which the current passes around the electro-magnet to the screw *m*, thence to the spring *n* in permanent contact with the barrel. As each tooth of the barrel during its rotary motion is brought into contact with a spring the current passes to one pair of electrodes which are ignited and drawn away to a distance that will break the current, the electro-magnet then ceasing to hold the armature its support is forced back by the spring which causes the arm to draw on the toothed wheel and bring the adjoining spring in contact with the next tooth upon the barrel thus igniting the electrodes in advance and in this way the light continuously runs the round of the buoys.

The fifth part of my invention relates to the introduction of an induction coil (formed either with or without a condensing arrangement) to be used in connection with a primary current, and one of my improvements herein consists in giving any required motion to electrodes by the operation of the primary current, and producing light by means of the induced current alone. I effect this operation by passing a primary current of voltaic or other electricity through one or more induction coils and at the same time move or regulate electrodes or their apparatus in any desired way. To produce the light I connect the electrodes with the secondary circuit of the coils, so that that current only shall pass through them and cause ignition. I prefer not to cut off or suspend the primary current but simply to change its direction by means of an electric reversing apparatus the construction of which is well understood. While therefore the light is developed by the secondary current the primary current does not cease to regulate the motion of the electrodes.

I perform the sixth part of my invention by combining the currents generated in an inductive coil with currents of magneto-electricity, produced by the motion of a conductor within the action of permanent magnets, so as to increase its effect in producing light.

The seventh part of my invention consists in a peculiar mode of obtaining the electric light by which signals are effected. It comprises the application and use of an electrotome or an arrangement of electrotomes, by which the current shall be let on both at rapid and at long intervals, or at rapid at short and at long intervals.
At each passage. of the current a distinct flash of light
4348 is produced, and this may be taken to denote an unit, the
short intervals the end of a number, and the long intervals to signify either the termination of the signal, as when a repetition of it is desired, or the end of a combination of numbers. This system may be made to represent words or sentences as well as numerals and being easily understood is well adapted to lighthouses.

Figure 4 represents a side view of an electrotome suitable for signalling the number three hundred and fifty-seven. It is placed on an axis which forms part of the circuit of the current and as it revolves in the direction of the arrows, by means of clockwork or other suitable power, the successive projecting teeth are brought at intervals according to their distance apart, in contact with a spring or moveable stud, thus closing the circuit and producing light between the electrodes with which it is in connection, as the distance to which the electrodes are separated breaks the current the light is extinguished until by the motion of the electrotome it is again renewed.

Lastly I propose to indicate to vessels by flashes of electric light, the depth of water in harbours or on banks and to effect this by means of a float within a tube, which by suitable mechanical contrivances as it rises and falls, calls into operation different electrotomes, and these by completing the circuit of the current give rise to flashes of light in number according to the depth of water in feet.

The manner in which I carry out this part of my invention will be understood on reference to the drawings numbered 5 and 6 sheet 3, *a* is a hollow pillar or tube, on the top of which the cap *b* is screwed—*c, c* are separate rows of insulated plates each plate being one foot long and connected by an insulated conductor to a rotary electrotome which corresponds by the number of flashes it is capable of calling forth, to the height in feet that the float *d*, will be from the bottom of the water when the brace spring *f* unites opposite plates. The electrotome is connected with one pole of a battery and one of the rows of insulated plates with the other pole. The pressure of the spring on the plates is regulated by the nut *g*. It will be evident that the post should be fixed sufficiently high above high-water mark to effect the required signals. Figure 6 represents a section of a revolving electrotome which would shew a depth of eleven feet.

To distinguish this from other marine lights I make it a colored light, by placing a colored glass before it, or by the use of my improved metal electrodes described in the first part of this my specification.

Having now described and particularly ascertained the nature of my said invention of improvements in obtaining light by electricity, and the manner in which the same is or may be used or carried into effect, I declare that I do not confine or restrict 4349 myself to the precise details or arrangements which I have described or referred to, as many variations may be made therefrom without deviating from the main features of my invention but I claim

First, the mode described of forming condensed gas-carbon electrodes for obtaining electric light.

Second, the use of the electrodes formed of compressed spongy or powdered metals, or of a combination of metal powder and plumbago or other form of carbon.

Third, the arrangement of electrodes and combination of mechanism or means for the production of a constant electric light as herein-before described in relation to the second part of this my said invention, reference being had to the figures on the annexed first sheet of drawings.

Fourth, the arrangements described of maintaining an uniform distance between a rotary disc electrode and a point or pencil electrode.

Fifth, the arrangements described relating to the fourth part of my said invention for producing a succession of flashes or streams of light, as well as the use of two or more negative electrodes in combination with a single positive electrode of mercury and the use of hollow negative electrodes in combination with a positive electrode of mercury.

Sixth, the plan described herein, by which any number of marine buoys or beacons may be successively illuminated.

Seventh, the arrangements or means for the production of electric light by the use of a secondary or induced current as described.

Eighth, the combination of magneto-electric with secondary currents for the production of light.

Ninth, the system or mode herein described in reference to the seventh part of my said invention for effecting signals by electric light.

And tenth, the arrangements described for indicating the depth of water by electric light.

In witness whereof I the said Charles Weightman Harrison have hereunto set my hand and seal this twenty-eighth day of August, one thousand eight hundred and fifty-seven.

CHAS. W. HARRISON. [L. S.]

4353 DEF'T'S EXHIBIT BURLEIGH & DANCHELL'S ENGLISH PATENT NO 3164 OF 1837. March 13, 1889. W. T. F., S. E. & N. P.

A. D. 1857, 24th December. No. 3164.

Manufacture of Articles from Plastic and other Materials.

Letters patent to Benjamin Burleigh, of 26 Great George street, Westminster, and Frederick Ludwig Danchell, of No. 452 Oxford street, in the county of Middlesex, for the invention of "certain improvements in the manufacture of vessels, plates, or utensils used for domestic, sanitary, electric, and manufacturing purposes."

Sealed the 18th June, 1858, and dated the 24th December, 1857.

Provisional specification left by the said Benjamin Burleigh and Frederick Ludwig Danchell at the office of the commissioners of patents with their petition on the 24th December, 1857.

We, Benjamin Burleigh, of 26 Great George street, Westminster, and Frederick Ludwig Danchell, of No. 452 Oxford street, in the county of Middlesex, do hereby declare the nature of the said invention for "certain improvements in the manufacture of vessels, plates, or utensils used for domestic, sanitary, electric, and manufacturing purposes" to be as follows:

4354 This invention has for its object the formation of articles of utility from various plastic and other material to be rendered solid by means of percussive force, stamping or hammering, and afterwards submitted to the action of heat in inclosed vessels.

It is proposed to take carbonaceous matter, such as coke, animal or vegetable charcoal, boghead ash, gas carbon, soot, lamp-black, clay, porcelain, sand, or other suitable material, each by itself or mixed, and rendered plastic by means of moist bituminous, resin-

ous, gummy, sac-harine, or glutinous substances, and to force the said materials into moulds suited for the object to be constructed by stamping or beating with suitable tools, by means of hand power or machinery, to the required degree of consistency or solidity. I propose to apply the above process in manufacturing articles of the following kinds, vizt: Meat safes, tanks, cisterns, casks, and other hollow vessels or receptacles for the purpose of preserving or purifying culinary or other substances, as well as water and other fluids; crucibles, retorts, assayers' muffles, muffle plates, cupolas; also cells, cyl*l*inders, plates, and el*l*ectrodes for electric purposes; receptacles and other articles for photographists; screens, respirators, and plates in general for purifying air; tubes, hollow or solid cyl*l*inders,
4355 columns, blocks, and similar objects for conducting fluids or
for building purposes; filtering mediums, charcoal pencils, tobacco pipes, moulds for casting metals, or articles used for manufacturing glass.

To render crucibles and other objects made of carbon proof against the action of oxygen when used in a fire, I cause the said articles to be coated outside with s*e*licious or other substance not liable to be acted upon by oxygen. To render vessels and other objects proposed to be manufactured impermeable to fluids and gases, I glaze or coat them with a varnish outside or inside, or both, when required.

Specification in pursuance of the conditions of the letters patent filed by the said Benjamin Burleigh and Frederick Ludwig Danchell in the Great Seal Patent Office on the 24th June, 1858.

To all — whom these presents shall come we, Benjamin Burleigh, of 26 Great George street. Westminster, and Frederick Ludwig Danchell, of No. 452 Oxford street, in the county of Middlesex, send greeting:

Whereas her most excellent majesty Queen Victoria, by her letters patent bearing date the twenty-fourth day of December, in the year of our Lord one thousand eight hundred and fifty-seven, in the twenty-first year of her reign, did, for herself, her heirs
4356 and successors, give and grant unto us, the said Benjamin
Burleigh and Frederick Lugwig Danchell, her special license that we, the said Benjamin Burleigh and Frederick Ludwig Danchell, our executors, administrators, and assigns, or such others as we, the said Benjamin Burleigh and Frederick Ludwig Danchell, our executors, administrators, and assigns, should at any time agree with and no others, from time to time and at all times thereafter during the term therein expressed, should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel Islands, and Isle of Man an invention for "certain improvements in the manufacture of vessels, plates, or utensils used for domestic, sanitary, electric, and manufacturing purposes," upon the condition (amongst others) that we, the said Benjamin Burleigh and Frederick Ludwig Danchell, our

executors or administrators, by an instrument in writing under our or their or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent:

4357 Now know ye that we, the said Benjamin Burleigh and Frederick Ludwig Danchell, do hereby declare the nature of our said invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement—that is to say:

This invention has for its object the formation of articles of utility from various plastic and other materials to be rendered solid by means of percussion force and afterwards submitted to the action of heat in closed vessels.

It is proposed to take carbonaceous matter, such as coke, animal or vegetable charcoal, boghead ash, gas carbon, lamp-black, or other suitable material, each by itself or mixed or rendered plastic by means of moist bituminous, resinous, gummy, oleaginous, saccharine, glutinous, or other suitable cementing medium, and to force the said materials into moulds suitable for the objects to be constructed by stamping or beating with suitable tools by means of machine or other power to the required degree of consistency or solidity, after which the objects are baked or burned in closed vessels.

We propose to apply the above process in manufacturing articles of the following kinds, viz: Meat safes, tanks, cisterns, casks, and other hollow vessels or receptacles for the purpose of preserving or purifying culinary and other substances, as well as water and
4358 other fluids, crucibles, retorts, assayers' muffles, muffle plates, cupolas; also cells, cylinders, plates for batteries, and electrodes for electro or galvanic purposes; receptacles and other articles for photographists, screens, respirators, and plates in general for purifying air, tubes, hollow or solid blocks, cylinders, columns, and similar objects for conducting fluids; filters, charcoal pencils, tobacco pipes, moulds for casting metals; also articles used in the manufacture or casting of glass.

To render crucibles and other objects made of solidified carbon proof against the action of oxygen when exposed to fire we cause the said articles to be coated outside with silicious glaze or other substance not liable to be acted upon by oxygen or atmospheric air.

To render vessels and other objects impermeable to fluids and gases we glaze them or coat them, either on the outside or inside, or on both sides, when required, with a varnish or lacker insoluble in the particular fluid or gas intended to be contained in the vessel.

Referring to the method of treating the carbonaceous substances herein described, it is further necessary to explain that either moist, bituminous, resinous, gummy, oleaginous, saccharine, or glutinous matters are mixed with pulverized carbonaceous substances, in order to make the particles thereof adhere together; but we cannot state the exact proportions of 4359 such mixture, as they differ according to degree of density of the object required to be produced. Generally, however, the proportion which the carbon bears to the plastic or cementing medium is about fifty per cent., and with regard to the mode of solidifying the material when placed in the mould we find the action of a steam hammer the most effective for the purpose, but we do not limit ourselves to this method, as the percussive action produced by another body accellerated by machine or other power may answer the purposes in many instances, and in some cases even hydraulic or screw pressure may be used. Any of the hollow vessels, receptacles, or other objects herein described may be made in one or in several parts, which parts may be joined together by means of suitable cement, screws, bolts, hoops, iron, wood, or other suitable casing.

Having thus described the nature of our invention and the manner of performing the same, we would have it understood that what we claim is—

Firstly. The mode of treating the materials by the use of percussive force produced by the steam hammer or other power as described for the production of the articles of utility herein specified.

Secondly. The application of solidified carbon to the manufacture of the articles of utility herein specified.

4360 Thirdly. The coating of objects of solidified carbon with glaze, as described, for the purpose of protecting them against the action of oxygen or atmospheric air when exposed to heat.

Fourthly. The coating of articles of solidified carbon with a suitable varnish, lacker, or glaze for the purpose of retaining fluids or gases.

In witness whereof we, the said Benjamin Burleigh and Frederick Ludwig Danchell, have hereunto set our hands and seals this twenty-fourth day of June, in the year of our Lord one thousand eight hundred and fifty-eight.

BENJ'N BURLEIGH. [L. S.]
FREDERICK LUDWIG DANCHELL. [L. S.]

4361 DEF'T'S EXHIBIT WAY ENGLISH PATENT NO. 2841 OF 1857.
Mar. 13, 1889. W. T. F., N. P. & S. E.

A. D. 1857, 10th November. No. 2841.

Obtaining Light by Electricity.

Letters patent to John Thomas Way, of Welbeck street, Cavendish square, in the county of Middlesex, for the invention of "improvements in obtaining light by electricity."

Sealed the 12th March, 1858, and dated the 10th November, 1857.

Provisional specification left by the said John Thomas Way at the office of the commissioners of patents with his petition on the 10th November, 1857.

I, John Thomas Way, of Welbeck street, Cavendish square, in the county of Middlesex, do hereby declare the nature of the invention for "improvements in obtaining light by electricity" to be as follows:

When a jet or jets of mercury connected with one pole of the battery is directed upon a point of charcoal or other conducting substance in connection with the other pole of the battery the charcoal or other conducting substance is liable to be consumed, in which case the focal distance is altered and the brilliancy of the light is impaired.

Now, one part of my invention consists in so arranging the charcoal of other conducting substance forming the solid electrode that it shall be continually renewed and presented to the steam of the flowing electrode at a constant distance from the orifice of
4362 the jet from which the latter issues. This may be effected in one or other of the following ways or otherwise: I arrange cylinders or rods of charcoal or other conducting material opposite to each other and cause them to be pressed together by springs or other convenient mechanism. Upon the point where the ends of the rods meet I direct the jet or jets of mercury, which, by proper means of adjustment, as described in my former patents, may be fixed at the focal distance or breaking point of the stream.

It is important that the pressure applied to the different rods of charcoal or other conducting material should be as nearly as possible the same. I sometimes employ for this purpose in place of springs the following arrangement: Cylinders of iron or steel or other suitable material are fitted with pistons, which in moving press the conducting rods against each other. At the back of these pistons mercury is introduced by pipes leading from a cistern above, and by this column of mercury the rods of charcoal or other conducting material are pressed forward with great equality. Instead of pressing rods of charcoal or other conducting substance against each other one such rod may be pressed against a piece of lime, phosphate of lime, or other comparatively infusible material, the flowing electrode being directed against the point of junction. A surface of charcoal or other conducting material, forming one electrode, may be presented at a constant distance from the ori- 4363 fice from which the flowing electrode issues by causing a cylinder or rod of each conductor upon which the flowing electrode is thrown to move forwards and on its axis, the required motion being given by suitable self-acting mechanism, or a rod of charcoal or other conducting material forming one of the electrodes may be projected by a spring or otherwise through a ring of iridium, so that as the end of the charcoal is consumed a fresh portion is pushed forwards in a similar manner to that in which the candle in Palmer's candle lamp is forced forwards as its end is consumed.

Another part of my invention consists in heating the material forming the flowing electrode before it is supplied to the jets.

Another part of my invention consists in adjusting the focal distance or breaking point of the flowing electrode by increasing or diminishing the pressure which causes it to issue from the jet.

Another part of my invention consists in a method of maintaining at a constant height above the jet the column of mercury or other flowing electrode. For this purpose, in conjunction with the open cistern from which the mercury flows, I employ a close cistern, from which the mercury is led by a pipe to the open cistern; this pipe dips slightly below the surface of the mercury in the open cistern. So soon, therefore, as the level of the mercury in the lower cistern is reduced the mercury will flow from the upper cistern, so that the pressure of mercury remains practically constant.

4364 Specification in pursuance of the conditions of the letters patent filed by the said John Thomas Way in the Great Seal Patent Office on the 10 May, 1858.

To all to whom these presents shall come I, John Thomas Way, of Welbeck street, Cavendish square, in the county of Middlesex, send greeting:

Whereas her most excellent majesty Queen Victoria, by her letters patent bearing date the tenth day of November, in the year of our Lord one thousand eight hundred and fifty-seven, in the twenty-first year of her reign, did, for herself, her heirs and successors, give and grant unto me, the said John Thomas Way, her special license that I, the said John Thomas Way, my executors, administrators, and assigns, or such others as I, the said John Thomas Way, my executors, administrators, and assigns, should at any time agree with, and no others, from time to time and at all times hereafter during the term therein expressed, should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel islands, and Isle of Man an invention for "improvements in obtaining light by electricity," upon the condition (amongst others) that I, the said John Thomas Way, my executors or administrators, by an instrument in writing under my or their or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent:

Now, know ye that I, the said John Thomas Way, do
4365 hereby declare the nature of the said invention and in what
manner the same is to be performed to be particularly described and ascertained in and by the following statement thereof—that is to say:

When a jet or jets of mercury connected with one pole of the battery is directed upon a point of charcoal or other conducting substance in connection with the other pole of the battery, the charcoal or other conducting substance is liable to be consumed, in which case the focal distance is altered and the brilliancy of the light is impaired.

Now, one part of my invention consists in so arranging the charcoal or other conducting substance forming the solid electrode that it shall be continually renewed and presented to the stream of the flowing electrode at a constant distance from the orifice of the jet from which the latter issues. This object may be effected in one or other of the following ways or otherwise: I arrange cylinders or rods of charcoal or other conducting material opposite to each other and cause them to be pressed together by springs or other convenient mechanism. Upon the point where the ends of the rods meet I direct the jet or jets of mercury, which, by proper means of adjustment as described in my former patents, may be fixed at the focal distance or breaking points of the stream.

Figure 1 is a longitudinal section of part of an electric lamp constructed in this manner. A A, tubes of iron; B B, pistons ground in, say, an inch long; C C, springs; D D, screw-nuts to open the
tube for charging; E, junction of the rods of charcoal; F,
4366 the jet; G, the stream of mercury.

It is important that the pressure applied to the different rods of charcoal or other conducting material should be as nearly as possible the same. I sometimes employ for this purpose in place of springs the following arrangement: Cylinders of iron or steel or other suitable material are fitted with pistons, which, in moving, press conducting rods against each other. At the back of these pistons mercury is introduced by pipes leading from a cistern above, and by this column of mercury the rods of charcoal or other conducting material are pressed forward with great equality. This arrangement is clearly shown at figure 2, which is also a longitudinal section of part of an electric light. A A, tubes of iron; B B, pistons ground in; C C, tubes connecting the tubes A A with a mercury cistern above; D D, screw-nuts to open the tubes A A for charging; E, junction of the rods of charcoal; F, the jet; G, the stream of mercury. The size (diameter) of the charcoals is dependent upon the strength of the battery, and the mercury current, about that of an ordinary le-d pencil or goose quil- or somewhat

smaller, is found to answer with a battery power of forty-eight cells of a Maynooth's battery, the zinc plates of which expose a surface of 60 inches each and a mercury stream of from 15 to 20 fluid ounc*h*es per hour, with a pressure of 18 to 24 inches. The lamp may be of the shape shewn in the drawings of my specification (No. 1258, 1856), the charcoals being introduced at the sides
4367 and the jet of mercury coming from the top and adjusted in
the manner shewn at figure 3, which is hereinafter described. Instead of pressing rods of charcoal or other conducting substances against each other, one such rod may be pressed against a piece of lime, phosphate of lime, or other comparatively infusible material, the flowing electrode being directed against the point of junction. In this case, when phosphate of lime is employed, it is prepared by precipitating phosphate of lime, moulding into a cylindrical form similar in size to the charcoal employed, and burning it. The cylinder of phosphate of lime is fixed in a suitable cup or boss of iron at the end of a rod or tube carried by the frame of the lamp.

A surface of charcoal or other conducting material forming one electrode may be presented at a constant distance from the orifice from which the flowing electrode issues by causing a cylinder or rod of such conductor, upon which the flowing electrode is thrown, to move forwards and on its axis, the required motion being given by suitable self-acting mechanism. For this purpose a rod or axis is mounted horizontally at the bottom of the lamp, and on this axis a cylinder of charcoal about 1½ to 2 inches in diameter is mounted, a hole being formed through the centre of the charcoal cylinder for the purpose. Motion is given to the axis by clock-work so that it may make about one-sixth of a revolution per minute, and on one end of the axis a screw is cut having about 10 threads to the
4368 inch, and this end of the axis passes through a fixed screw-
nut so that as the axis revolves it is constrained also to move forwards endwise; thus a fresh surface is constantly offered to the flowing electrode; or a rod of charcoal or other conducting material forming one of the electrodes may be projected by a spring or otherwise through a ring of iridium, so that as the end of the charcoal is consumed a fresh portion is pushed forwards in a similar manner to that in which the candle in Palmer's candle lamp is forced forwards as its end is consumed. Figure 3 is a vertical section of a lamp constructed in this manner. *a* is an iron tube communicating at its upper end with a reservoir of mercury and carrying at its lower end a jet of fire-clay, *b*, cemented into it. On the exterior of the tube *a* a screw-thread is cut, and it has on it the nut *c*, by turning which the jet at the end of the tube is raised and lowered to adjust the focus. *d* is an exterior tube, through which the tube *a* can slide freely. A cap, *e*, screws onto the upper end of the tube *d*, and by nipping the flange at the lower part of the nut *c* clamps the tube *a* and the tube *d* together. On the lower end of the tube *d* a ball, *f*, is formed, which fits into a socket formed at the upper part of the cap *g*, and it can be clamped in any position in this socket by screwing down the piece *h* upon it; thus facility is afforded for the horizontal adjustment of the position of the jet. *i* is

a glass cemented at its upper end into the cap *g* and at its lower end into the metal ring *j*, which screws onto
4369 the bottom *k*. Through the centre of this piece a hole is
drilled of sufficient size to receive the charcoal rod *l*, which is pressed constantly upward by the spiral spring *m*, contained in a metal tube screwed into the pieces *k*, and the upper end of the charcoal rod *l* is prevented from rising above its proper position by a cap of fire-clay, *m'*, carrying a ring of irid-um of smaller diameter than the charcoal rod. This ring of irid-um is shown separately at figures 4. It will be seen that it is furnished with four projections, which are embedded in the fire-clay of the cap *m'* before it is burnt. I would remark that it is not necessary that the irid-um ring should be formed in one piece of metal; a series of points of that metal embedded in the fire-clay cap and ranged in a circle round the central ap*p*erture and projecting inwards, so as to come in contact with the upper end of the charcoal, succeeds equally well. It is only necessary that the metal should abut*t* on the cylinder of charcoal at a sufficient number of points in a circle round its axis to retain it truly in its place. Figure 5 is a plan of a cap, *m'*, in which three only of such points are employed, and a cap formed in this manner I find to succeed well in practice. The mercury from the jet escapes by the pipe *n* and is received into a vessel, *o*. At the end of the metal tube containing the spiral spring is a screw-cap, *p*, by removing which access may be obtained to the spring. *q q* are strengthening wires passing from the ring *j* to the cap *g;* they are
4370 insulated from the cap *g* by passing through collars of ivory
r r.

When the lamp is in use the wires from the two poles of the battery are clamped to the apparatus at *s* and *t*, and the mercury jet is adjusted so that the stream of metal falls on the end of the charcoal rod *l* before or about the point where it breaks into drops.

Another part of my invention consists in heating the material forming the electrode before it is supplied to the jets. For this purpose I arrange, under the iron cistern from which the jet is supplied, a gas or other lamp, and I so regulate the lamp as to heat the mercury as much as possible without producing an injurious amount of evaporation.

Another part of my invention consists in adjusting the focal distance or breaking point of the flowing electrode by increasing or diminishing the pressure which causes it to issue from the jet. For this purpose I connect the cistern with a jet by means of jointed iron or flexible tubes, and in place of fixing the cistern in its position with respect to the lamp I suspend the cistern from a standard by means of a cord passing over a pulley at the upper part of the standard and descending to a barrel, on which the cord can be wound so as to lift the cistern to a greater or less height, and by so raising or lowering the cistern the breaking point of the jet can be adjusted. The bar'l can be fixed in any position by means of a click dropping into the teeth of a ratchet wheel fixed on the
4371 axis of the barrel.

Another part of my invention consists in a method of maintaining at a constant height above the jet the column of mercury or other flowing electrode. For this purpose, in conjunction with the open cistern from which the mercury flows, I employ a close cistern, from which the mercury is led by a pipe to the open cistern. This pipe dips slightly below the surface of the mercury in the open cistern. So soon, therefore, as the level of the mercury in the lower cistern is reduced the mercury will flow from the upper cistern, so that the pressure of mercury remains practically constant. This arrangement is shown at figure 6. A is the cistern, having well-ground stop-cocks at D and E. Mercury is introduced into the cistern C by the funnel F. The stop-cock D is then closed, and upon opening the stop-cock E mercury flows till the cistern A is filled up to the mouth of the tube. As the mercury in the cistern is drawn off through B it will be regularly replaced from the upper cistern. The cisterns may be of any convenient size, but the cistern C, with the pipe leading from it, cannot, of course, exceed 30 inches in height. It has been assumed in the present specification that the source of electricity employed in the mercurial light is a battery. Any arrangement by which current electricity is obtained, such, for instance, as a magneto-electric machine, is equally applicable to this form of light.

4372 In witness whereof I, the said John Thomas Way, have hereunto set my hand and seal this eighth day of May, in the year of our Lord one thousand eight hundred and fifty-eight.

J. THOMAS WAY. [L. S.]

4377 (Third edition.)

A. D. 1872, 16th December. No. 3809.

Electric Light.

Letters patent to Stanislas Wikentjevitsch Konn, of the firm of S. A. Kosloff and Company, of Great Winchester Street buildings, in the city of London, and of St. Petersburgh, in the Empire of Russia, for the invention of "improvements in the means and appliances for the production and maintaining of light by electricity." A communication from abroad by Alexandre Nicolaevitsch Ladiguine, of St. Petersburgh.

Sealed the 4th February, 1873, and dated the 16th December, 1872.

Provisional specification left by the said Stanislas Wikentjevitsch Konn at the office of the commissioners of patents with his petition on the 16th December, 1872.

I Stanislas Wikentjevitsch Konn of the firm of S. A. Kosloff and Company of Great Winchester Street buildings in the city of London and of St. Petersburgh in the Empire of Russia do hereby declare the nature of the said invention for "improvements in the means and appliances for the production and maintaining of light by electricity" to be as follows:—

Hitherto the ordinary manner of producing the electric light has been to bring the points of two bad conductors of electricity
4378 into proximity with each other when the intense heat produced by the chemical reaction caused by the contact of the electricity with the oxygen of the atmosphere brought about the ignition of the carbon and the production of an intense light.

This invention consists in a novel method of producing the electric light by taking advantage of the property possessed by the electric current of pumping so to speak the conductors whereby many of the disadvantages of the former method are avoided. The current instead of by a chemical reaction causing the ignition of the conductor points, merely carries a portion of the conductor to a red heat by the simple action of caloric.

One or more of the conductors which are preferably of graphite are enclosed in a species of lantern hermetically closed and filled with nitrogen or other gas that does not support combustion and are maintained therein by any convenient method of support. To produce the electric current an ordinary magneto-electric machine such as those of Wild Noble and others is employed and the current is led into the lantern by means of a wire to one of the graphite conductors (when the lantern contains more than one) and in passing through the conductor the electricity heats it to redness and causes it to give out a brilliant light. The current is then led to the second graphite conductor and passing through that producing a similar effect is led to a third and so on until all the conductors in the particular lamp have been illuminated when the current is led to those in the next lamp and so *on* to the end of the series which may consist of hundreds of conductors or lamps.

If it should be desired not to illuminate some of the lanterns of the series an arrangement is provided to each of them whereby this can be effected.

By this method of producing the electric illumination a continuous and steady lighting in one or more lamps is effected, a great economy is produced by the non-consumption of the conductor and a flame which is not injurious to the eyes is obtained.

4379 Specification in pursuance of the conditions of the letters patent filed by the said Stanislas Wikentjevitsch Konn in the Great Seal Patent Office on the 16th June, 1873.

To all to whom these presents shall come I, Stanislas Wikentjevitsch Konn, of the firm of S. A. Kosloff and Company, of Great Winchester Street buildings, in the city of London, and of Saint Petersburgh, in the Empire of Russia, send greeting:

Whereas her most excellent majesty Queen Victoria by her letters patent bearing date the sixteenth day of December in the year of our Lord one thousand eight hundred and seventy-two in the thirty-sixth year of her reign did for herself her heirs and successors give and grant unto me the said Stanislas Wikentjevitsch Konn her special licence that I the said Stanislas Wikentjevitsch Konn my executors administrators and assigns or such others as I the said Stanislas Wikentjevitsch Konn my executors administrators and assigns should at any time agree with and no others from time to time and at all times thereafter during the term therein expressed should and lawfully might make, use, exercise, and vend, within the United Kingdom, of Great Britain and Ireland, the Channel islands, and Isle of Man, an invention for "improvements in the means and appliances for the production and maintaining of light by electricity," communicated to me from abroad by Alexandre Nicolaevitsch Ladiguine of Saint Petersburgh upon the condition (amongst others) that I the said Stanislas Wikentjevitsch Konn my executors or administrators by an instrument in writing under my, or their, or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent.

Now know ye that I the said Stanislas Wikentjevitsch Konn do hereby declare the nature of my said invention, and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement thereof reference being had to the drawings hereunto annexed that is to say.

Hitherto the ordinary manner of producing the electric light has
been to bring the points of two bad conductors of electrcity
4380 into proximity with each other when the intense heat produced by the chemical reaction caused by the contact of the electricity with the oxygen of the atmosphere brought about the ignition of the carbon and the production of intense light.

This invention consists in a novel method of producing the electric light by taking advantage of the property possessed by the electric current of pumping so to speak the conductors whereby many of the disadvantages of the former method are avoided. The current instead of by a chemical reaction causing the ignition of the conductor points merely carries a portion of the conductor to a red heat by the simple action of caloric.

One or more conductors which are preferably graphite are enclosed in a species of lantern hermetically closed and filled with nitrogen or other gas that does not support combustion and are maintained therein by any convenient method of support. To produce the electric current an ordinary magneto-electric machine such as those of Wild Noble and others is employed and the current is led into the lantern by means of a wire to one of the graphite conductors (when the lantern contains more than one), and in passing through the conductor the electricity heats it to redness and causes it to give out a brilliant light. The current is then led to the second graphite conductor, and passing through that producing a similar effect is led to a third and so on until all the conductors in the particular lamp have been illuminated when the current is led to those in the next lamp and so on to the end of the series which may consist of hundreds of conductors or lamps.

If it should be desired not to illuminate some of the lanterns of the series an arrangement is provided to each of them whereby this can be effected.

By this method of producing the electric light a continuous and steady illumination in one or any number of lamps is effected a great economy is produced by the non-consumption of the conductor, and a flame which is not injurious to the eyes is obtained.

The invention will be understood by reference to the accompanying drawings, and by the following detailed description thereof.

Figures 1 and 2 are views of a lantern, with respectively one and
two of the carbon stems arranged in the interior. Figure 3 is
4381 an outside view of the lantern with two stems, figure 4 is a
plan view of the same, figure 5 is a plan view taken through

the line A, B, of figure 2, figure 6 is a plan view taken through the line C D of figure 1, while figure 7 is a separate view of the carbon stem which I prefer to use for these sorts of lanterns. The stem is composed of graphite or a composition of the usual description compressed or formed with a reduced diameter at or near its central part as at *b* the ends *c c* being of larger diameter and clipped or held in socket frames *d d* which pass through the lantern ends *e e* and are connected to the circuit wires from the magnets or from the battery. Any number of the carbon stems can be employed in the same lantern and the current of electricity may be made to pass from one stem to another until the whole or any two or more of them are charged for lighting as desired. The lanterns are composed of the two ends *e e* the lips of which receive the glass *f* of the required shape and in such a manner that the whole can be hermetically closed for preventing electrical contact with the atmosphere, which is essential for the purposes of practically carrying the invention in effect and in order to fulfil this object more completely the lanterns are charged with nitrogen or other gas which does not support combustion.

In some cases I connect the two wires or frames of neighbouring stems by a claw attachment *g* (figures 2 and 3) which is free to be turned on its pin or stud *h* for its claw to engage over or upon the pin or stud *i* of the other and I establish the continuity of the electric current from one frame to the next by that means.

In other cases if desirable I fit a metallic strip or wire *k* to the two ends of the lanterns as in figure 1 to put the two ends in connection.

To ensure the passage of the electric current in the proper direction I insulate the lantern ends by means of glass or other non-conductable body arranged upon the socket frames so as to close the openings through which the stems are inserted as will be understood.

Figure 8 is a section, and figure 9 a plan view with the top cap removed of another form of lamp or lantern. In this lamp the carbon stem is V shaped, the electric current passing down one side and up the other side of the V the light being formed at the angle at the bottom. This stem is suitably supported and enclosed
4382 in a glass lamp or case filled with nitrogen or gas incapable
of supporting combustion as before and the current of electricity is applied as in the first instance or in any convenient manner.

And having now described the nature of the said invention and in what manner the same is to be performed I declare that I claim,—

Firstly, the production of light by electricity from carbon stems enclosed in a case charged with a non-supporter of combustion and hermetically closed substantially in the manner hereinbefore described.

Secondly, the apparatus shewn in figures 1 to 7 of the accompanying drawings in which light is produced by electricity from carbon stems hermetically closed in a vessel charged with a non-supporter of combustion as described and

Thirdly I claim the modified arrangement of carbon stem described and shown with reference to figures 8 and 9 of the accompanying drawings.

In witness whereof I the said Stanislas Wikentjevitsch Konn, have hereunto set my hand and seal this fifth day of June one thousand eight hundred and seventy-three.

STANISLAS WIKENTJEVITSCH KONN. [L. S.]

4384 DEF'T'S EXHIBIT KONN'S ENGLISH PATENT NO. 91 OF 1873.
Mar. 31, '89. W. T. F., S. E.

A. D. 1873, 8th January. No. 91.

Producing Heat by Electricity.

Letters patent to Stanislas Wikentjevitch Konn, of the firm of S. A. Kosloff and Company, of Great Winchester Street buildings, and of St. Petersburgh, in the Empire of Russia, for the invention of "improvements in producing heat by electricity." A communication from abroad by Alexandre Nicolaevitch Ladighin, of St. Petersburgh, in the Empire of Russia.

Sealed the 25th February, 1873, and dated the 8th January, 1873.

Provisional specification left by the said Stanislas Wikentjevitch Konn at the office of the commissioners of patents with his petition on the 8th January, 1873.

I, Stanislas Wikentjevitch Konn, of the firm of S. A. Kosloff and Company, of Great Winchester Street buildings, and of St. Petersburgh, in the Empire of Russia, do hereby declare the nature of the said invention for "improvements in producing heat by electricity" to be as follows:

This invention relates to the production of heat by electricity by the employment of solid stems of carbon within hermetically closed vessels in which azotic or other gas is present.

The stems of carbon are of varied diameters in their length,
4385 and the heat is thrown off from them at their smaller parts,
preferably at about their centres, the contact or circuit being established between them by claws or pins, the removal of which breaks the contact when desired. The electric current is produced by an electro-magnetic apparatus such as that known as Wild's or Noble's, and the heat is maintained so long as the current is kept up. The azotic gas employed is of such a nature when hermetically enclosed in a vessel that the carbon stems are not decomposed

by it. Consequently they do not burn away, as is known to be the case where two carbon points have been used for the purpose.

Several apparatus can be enclosed in an outer casing into which atmospheric air can be forced and which after being heated to the desired degree can be spread or distributed into apartments, factories, or into ovens, drying sheds, or places in which the heat is required.

Specification in pursuance of the conditions of the letters patent filed by the said Stanislas Wikentjevitch Konn in the Great Seal Patent Office on the 8th July, 1873.

To all to whom these presents shall come I, Stanislas Wikentjevitch Konn, of the firm of S. A. Kosloff and Company, of Great Winchester Street buildings, and of Saint Petersburgh, in the Empire of Russia, send greeting:

4386 Whereas her most excellent majesty Queen Victoria, by her letters patent bearing date the eighth day of January, in the year of our Lord one thousand eight hundred and seventy-three, in the thirty-sixth year of her reign, did, for herself, her heirs and successors, give and grant unto me, the said Stanislas Wikentjevitch Konn, her special license that I, the said Stanislas Wikentjevitch Konn, my executors, administrators, and assigns, or such others as I, the said Stanislas Wikentjevitch Konn, my executors, administrators, and assigns, should at any time agree with and no others, from time to time and at all times thereafter during the term therein expressed should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel islands, and Isle of Man an invention for "improvements in producing heat by electricity," communicated to me from abroad by Alexandre Nicolaievitch Ladighin, of Saint Petersburgh, in the Empire of Russia, upon the condition (amongst others) that I, the said Stanislas Wikentjevitch Konn, my executors or administrators, by an instrument in writing under my or their or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal
4387 Patent Office within six calendar months next and immediately after the date of the said letters patent:

Now know ye that I, the said Stanislas Wikentjevitch Konn, do hereby declare the nature of my said invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement thereof, reference being had to the drawings hereunto annexed, that is to say—

This invention relates to the production of heat by electricity by the employment of solid stems of carbon within hermetically closed vessels, charged with azotic or other gas, which does not support combustion.

The stems of carbon may be of varied diameters in their length, and the heat is thrown off from them, preferably, at about their centres, the contact or circuit being established between them by claws on pins, the removal of which breaks the contact when desired. The electric current is produced by an electro-magnetic apparatus, those known as Wilde's or Noble's being preferred, and the heat is maintained so long as the current is kept up. The azotic gas hermetically enclosed in the vessel in which the carbon stems are prevents their decomposition, and consequently they do not burn away, as is the case where two carbon points in contact with the atmosphere have been used for production of light.

4388 Several apparatus can be enclosed in an outer casing, into which atmospheric air can be forced and which after being heated to the desired degree can be spread or distributed into apartments, factories, or into ovens, drying sheds, or places in which the heat is required or into boilers for heating the water direct.

The invention will be well understood on reference to the accompanying drawings, in which figure 1 is a section of a carbon steam enclosed in its case.

Figure 2 is a plan view of a vessel or box, in which are placed several stems or apparatus in electrical connection with one another, while figure 3 is a side view of the same, showing a portion of the case removed.

The carbon stem *a* of smaller diameter in its middle is fixed firmly in the metal case *b* in any convenient manner, the case being filled with azotic gas (nitrogen) or other gas which does not support combustion and hermetically closed. Several of the carbon stems and their cases are enclosed in a metal vessel or box, *d*, and the electrical circuit is established between them by the claws *e*, which turn freely upon pins *f*, so that the circuit can be interrupted when desired. The electricity is led into the box or case by means of the first claw *f′*, to which is attached the wire from the battery or magneto machine. At each side of the vessel *d* is a cylin-
4389 drical aperture, *g h*, the one *g* for the entry of air and the other *h* for its exit. On the electric current being caused to pass continuously from the battery into the claw *f′* and thence successively through all the carbon stems, the latter, becoming incandescent or red hot, develop an enormous heat, so that the air entering through the aperture *g*, after circulating among all the cases *b*, becomes warmed and, proceeding out through the aperture *h*, is led away to any place where it may be required. In consequence of the carbon stems being surrounded by a non-supporter of combustion it is impossible for them to consume, however long or however often may be the passage of the electric fluid through them and their consequent incandescence.

Figures 4 and 5 show the invention as applied to the heating of water in steam boilers, being respectively a longitudinal and transverse section of a steam boiler with the invention applied to it. In this case a tube or tubes, *i*, is fitted in the boiler above the water level, and along its whole length from these tubes *i* proceed other tubes *j* into the boiler, to the ends of which the cases *b*, hermetically closed and containing the carbon stems surrounded by a gas which does not support combustion, are suspended. The wire from the electric battery is led into this tube *i* and down each of the tubes *j* to the carbon stems and up again to the next carbon stem, so 4390 that upon the current being sent continuously it passes through all the stems and keeps them in a state of incandescence, and by the intense heat developed the water in the boiler is rapidly raised to the boiling point.

In figure 5 the method in which it is preferred to support the tubes *i* is shown. To the top of the boiler is secured an arm, *k*, which ends in each side in a semicircular holding clip and cap with flanges at the side through which bolt-holes are made, and the tube *i* being passed between the semicircular clip and cap, they are then bolted together and thus the tube *i* is firmly held.

Figure 6 is a transverse section of a boiler showing another form of case containing the carbon stem.

Figures 7 and 8 show a section and plan view — a heating apparatus in which the carbon stem is of V shape. In this case the electric current passes down one side of the V and up the other, and in other respects the apparatus is precisely similar to those already explained; it is evident that stems of other shapes may be used.

Having now described the nature of the said invention and in what manner the same is to be performed, I declare that I claim:

Firstly. The production of heat by electricity by means of single solid carbon stems enclosed in a vessel charged with a non-4391 supporter of combustion and hermetically closed, substantially as described and shown.

Secondly. The arrangement of apparatus, shown in figures 1, 2, and 3 of the drawings, whereby air is heated, substantially as described and shown.

Thirdly. The arrangements of apparatus, shown in figures 4, 5, and 6, for heating the water on steam boilers, substantially as described and shown.

And lastly. I claim heating liquids by electrical heaters immerced or submerged therein, substantially as described.

In witness whereof I, the said Stanislas Wikentjevitch Konn, have hereunto set my hand and seal this fourth day of July, one thousand eight hundred and seventy-three.

4394 DEF'T'S EXHIBIT KOSLOFF'S ENGLISH PATENT NO. 441 OF 1875. W. T. F., S. E.

A. D. 1875, 5th February. No. 441.

Production of Electric Light.

Letters patent to Stephen Alexandrovitch Kosloff, of St. Petersburg, in the Empire of Russia, but at present of the city of London, for the invention of "improvements in the production of electric light and in apparatus therefor."

Sealed the 2nd April, 1875, and dated the 5th February, 1875.

Provisional specification left by the said Stephen Alexandrovitch Kosloff at the office of the commissioner of patents with his petition on the 5th February, 1875.

I, Stephen Alexandrovitch Kosloff, of St. Petersburg, in the Empire of Russia, but at present of the city of London, do hereby declare the nature of the said invention for "improvements in the production of electric light and in apparatus therefor" to be as follows:

These improvements consist essentially in the subdivision of the electric light which is produced by means of an electric current heating to a white heat sticks of carbon placed in the circuit and being hermetically enclosed in a globe filled with nitrogen gas, all as hereinafter set forth.

1st. The unequal expansion by heat of different substances
4395 employed in electric light apparatus has not been hitherto
sufficiently considered by other inventors. They therefore placed their carbons on metal conductors which served as supports and fix- them firmly thereto, either by pinchers or by being screwed to the same or by other means. This way of joining together two different substances subject to different temperatures produced the breakage of the carbon, the latter not expanding in the same ratio as the metal, or because, the expansion of the metal being greater than that of the carbon, the metal in heating detaches itself gradually from the carbon and produced electric sparks. In my system the carbon is placed between two insulating supports, either of china, clay, crystal, calcined magnesia, or other insulating substances, the carbon fitting in and being allowed to move a little in the hollow of the said supports.

2d. Every metal which is outwardly attached, screwed, or fixed in any other way to the carbon detaches itself in heating and produces electric sparks and consequently the melting of the metal. In my system I introduce the metal wires into the carbon, which gives me a better contact when the carbon is heated by the current and does not produce electric sparks; but in order not to put the
metal into direct contact with the white-hot carbon, thicker
4396 end pieces of carbon with holes crosswise (that is to say,
through the length and the thickness) serve as communi-

cators of the electric current, and these thicker pieces of carbon, not being such bad conductors as the thinner sticks of carbon which are destined to give the light and fit into the thicker pieces of carbon, heat to a lesser degree the metal introduced into them.

3rd. The connection of the principal conductors with the metallic —, which are introduced into the thick end pieces of carbon, I effect by means of hinges or fastenings of fine twisted metallic wire, leaving a little space to move about in case of dilatation, and resting thereon with their own weight. I thus obtain a sufficient contact without producing electric sparks. My connections cannot increase the loss of electric current, because the heat produced by an electric current passing through two pieces of metal not firmly attached to each other, but closely touching each other, is much smaller than the heat caused to my connections by the contact with a white-hot body in a high temperature.

4th. In order to avoid the inconvenience of the preparation of nitrogen gas and its introduction into the lamp after the air has been withdrawn from it, I, according to my invention, produce the gas by rar*i*fying the air in the globe in which the apparatus
4397 is placed by means of the carbon itself, which is heated by
the electric current, and which at the same time is to give me the light. By dilating the air, which could not occupy the same space in the globe, it is caused to escape out of the globe through a valve or valves, and then cannot re-enter the globe. The small quantity of oxygen remaining in the rar*i*fied air in the globe is transformed into oxide of carbon. In order to have as little air as possible in my lamps I fill the superfluous space in the globe with massive pieces or pieces in the shape of tubes closed at one end of china, clay, calcined magnesia, crystal, or any other insulating substance, with a hollow through their whole length for their metallic conductors or even with carbons, with insulators, instead of employing metallic conductors. I also make use of these massive pieces as supports for the carbon bearers of the sticks of carbon which are destined to give the light. If I make the said filling pieces as insulated pieces of carbon, carbon connections may be employed for connecting with the thin carbon sticks. The globe and the said massive pieces must be of sufficient length, according to the strength of the light which it is intended to produce, in order that the valve or valves may not be exposed to too great a heat and
4398 in order that by employing a hydraulic joint or closing of
any liquid which, being exposed to a certain heat, does not produce vapors which would consume the carbon. I altogether avoid mercury as being dangerous to the health. The said massive pieces may also be of metal, but in that case I introduce insulators in order that the currents may meet in the sticks of carbon.

5th. When I have not at my disposal a stronger electric source to enable me to light thicker sticks of carbon, then I place several thin sticks of carbon in the same lamp, and I light them successively the one after the other, and in order to cause the electric current to pass automatically from one carbon to another I employ the following system: I introduce the metallic wires which traverse

the thick pieces of carbon, not at the same height, but gradually a little lower than in the preceding piece of carbon. In case of breakage of one of the lighted carbons the thick piece of carbon, being fastened on one side only, will incline through its weight toward the wire extending in the shape of a ring from the second carbon, and, having a wire in the form of a hook or a plate, place itself into the ring of the second carbon. The current being interrupted in the first carbon is communicated to the second carbon, and
4399 from the second to the third, and so forth.

In lamps with several carbons the insulators between which the thick pieces of carbon repose are of a round shape, with a small opening to allow guards to be placed into them, which prevent the thicker pieces of carbon from descending lower than they ought. After having *out* the carbon into its place the opening is shut up by means of a bolt or hook.

In lamps with several carbons one pole is in communication with one end of all the carbons, while the other pole is put into communication with all the carbons which are to be lighted first—that is to say, with the carbons where the aforesaid metallic wire is highest.

If I do not want to make use of the automatic mechanism in the lamps with several carbons I employ a commutator, where one pole is in communication with the one end of all the carbons, whilst the other pole may be put into connection with each series of carbons in the different lamps having separate conductors.

The system of placing the lamps into the circuit may be effected in two ways, namely, either by placing one series of lamps united by a metallic wire in such a way that the current traverses
4400 all the carbons, the conductor of one pole being in communication with the first lamp and the conductor of the other pole in communication with the last lamp, or by subdividing the current—that is to say, the current of one pole is subdivided from one point and conducts the current by separate conductors to each lamp. The current of the other pole, subdivided in the same way, meets the current of the first pole in each lamp.

Specification filed in pursuance of the conditions of the letters patent and of an order of the lord chancellor by the said Stephen Alexandrovitch Kosloff in the Great Seal Patent Office on the 26th August, 1875.

To all to whom these presents shall come I, Stephen Alexandrovitch Kosloff, of St. Petersburg, in the Empire of Russia, but at present of the city of London, send greeting:

Whereas her most excellent majesty Queen Victoria, by her letters patent bearing date the fifth day of February, in the year of our Lord one thousand eight hundred and seventy-five, in the thirty-eighth year of her reign, did, for herself, her heirs and successors, give and grant unto me, the said Stephen Alexandrovitch Kosloff, her special license that I, the said Stephen Alexandrovitch Kosloff,

my executors, administrators, and assigns, or such others as
4401 I, the said Stephen Alexandrovitch Kosloff, my executors, administrators, and assigns, should at any time agree with, and no others, from time to time and at all times thereafter during the term therein expressed, should and lawfully might make, use, exercise, and vend within the United Kindom of Great Britain and Ireland, the Lamel islands, the Isle of Man an invention for "improvements in the production of electric light and in apparatus therefor," upon the condition (amongst others) that I, the said Stephen Alexandrovitch Kosloff, my executors or administrators, by an instrument in writing under my or their or one of their hands and seals, should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent:

Now, know ye that I, the said Stephen Alexandrovitch Kosloff, do hereby declare the nature of my said invention and in what manner the samé is to be performed to be particularly described and ascertained in and by the following statement, reference being had to the accompanying drawings and to the letters of reference marked thereon—that is to say:

4402 These improvements consist essentially in the subdivision of the electric light, which is produced by means of an electric current heating to a white heat sticks of carbon placed in the circuit and being hermetically enclosed in a globe filled with nitrogen gas, all as hereinafter set forth.

First. The unequal expansion by heat of different substances employed in electric light apparatus has not been hitherto sufficiently considered by other inventors. They therefore place- their carbons on metal conductors, which serve as supports, and fixed them firmly thereto either by pinchers or by being screwed to the same or by other means. This way of joining together two different substances subject to different temperatures produced the breakage of the carbon, the latter not expanding in the same ratio as the metal, or because the expansion of the metal being greater than that of the carbon the metal in heating detached itself gradually from the carbon and produced electric sparks. In my system, as illustrated upon the appended sheet of drawings at figure 1, the carbon A and B are placed between two insulating supports C D, either of china, clay, crystal, calcined magnesia, or other insulating substances, the carbons *a* fitting in and being allowed to move a little in the hollow of the said supports C D.

4403 Second. Every metal which is outwardly attached, screwed, or fixed in any other way to the carbon detaches itself in heating and produces electric sparks, and consequently the melting of the metal. In my system I introduce the metal wires E E′ (see figure 2) into the carbon A, which gives me a better contact when the carbon is heated by the current and does not produce electric sparks. In order not to put the metal into direct contact with the white-hot carbon I employ the thicker end pieces A of carbon with holes crosswise, which serve as communicators of the electric current to the smaller carbon sticks B, and these thicker pieces of carbon A not being such bad conductors as the thinner sticks of carbon B, which are destined to give the light and which fit into the thicker pieces of carbon A, heat to a lesser degree the metal introduced into them. These insulators C D are secured to a screwed support or standard F by means of the nuts G G′ and H, the whole being placed upon a seat I.

Third. The connection of the principal conductors with the metallic wires E E′, which are introduced into the thick end pieces of carbon, is illustrated at figure 3, and consists of hinges or fastenings J J′ of fine twisted metallic wires, which are placed upon the metallic conductors K K′ from the different poles and held there at
the required height by nuts M, their other ends being
4404 placed upon the wires E E′, nuts N preventing them from
coming off, but leaving a little space to move about in case of dilatation, the hinges resting on the wires with their own weight. I thus obtain a sufficient contact without producing electric sparks. My connections cannot increase the loss of electric current, because the heat produced by an electric current passing through two pieces of metal not firmly attached to each other, but closely touching each other, is much smaller than the heat caused by any connections by the contact with a white-hot body in a high temperature.

Fourth. In order to avoid the inconvenience of the preparation of nitrogen gas and its introduction into the lamp after the air has been withdrawn from it according to my invention I produce the gas by rar*i*fying the air in the globe in which the apparatus is placed by means of the carbon itself, which is heated by the electric current and which at the same time is to give the light. This part of my invention is shown at figure 4. By dilating the air, which could not occupy the same space in the globe O, it is caused to escape out of the globe O through a valve or valves, P, so arranged as to admit of the passage of air out of, but not into, the globe O. The small quantity of oxygen remaining in the rar*i*fied air in the
globe is transformed into oxide of carbon. In order to have
4405 as little air as possible in my lamp I fill the superfluous space
in the globe with massive pieces Q or pieces in the shape of tubes, closed at one end, of china clay, calcined magnesia, crystal, or any other insulating substance, with a hollow through their whole length for their metallic conductors or even with carbon with insulators instead of employing metallic conductors. I also make use of these massive pieces as supports for the carbon bearers of the sticks of carbon which are destined to give the light. If I make the said filling pieces as insulated pieces of carbon, carbon connections may be employed for connecting with the thin carbon sticks. The globe O and the said massive pieces Q must be of sufficient length, according to the strength of the light which it is intended to produce, in order that the valve or valves P may not be exposed to too great a heat and in order to avoid vaporization when I employ a hydraulic seal joint or closing of any liquid which being exposed to a certain heat does not produce vapors which would con-

sume the carbon. I altogether avoid mercury as being dangerous to the health. The said massive piece or pieces Q may also be of metal, but in that case I introduce insulators in order that the current may meet in the sticks of the carbon. The lower part of the globe O is situated in a reservoir, R. A lid, S, is provided, and springs T attached thereto hold the globe in position; *u u′* 4406 are conductors in the form of an incrusted metallic piece, and are put in communication with external conductors by means of metallic buttons V.

Figure 5 shows an arrangement which I employ when I have not at my disposal a sufficiently strong electric source to enable me to light thicker sticks of carbon; then I place several thin sticks of carbon into the same lamp, and I light them successively the one after the other, and in order to cause the electric current to pass automatically from one carbon to another I employ the following system: I introduce the metallic wires E E′, which traverse the stick pieces of carbon A, not at the same height, but gradually a little lower than in the preceding piece of carbon. In case of breakage of one of the lighted carbons B, the thick piece of carbon A, being fastened on one side only, will incline through its own weight towards the wire E^2 (extending in the shape of a ring from the second carbon), and having a wire in the form of a hook or a plate and place itself into the ring of the second carbon. The current, being interrupted in the first carbon, is communicated to the second carbon, and from the second to the third, and so forth.

In lamps with several carbons the insulators between which the thick pieces of carbon repose are of a round shape, with a small opening to allow guards to be placed into them, which prevent the thicker pieces of carbon from descending lower than they ought.

After having put the carbon into its place the opening is shut
4407 up by means of a bolt or hook.

In lamps with several carbons one pole is in communication with one end of all the carbons, whilst the other pole is put into communication with all the carbons which are to be lighted first—that is to say, with the carbons where the aforesaid metallic wire is highest.

If I do not want to make use of the automatic mechanism in the lamps with several carbons, as described with reference to figure 5, I employ a commutator where one pole is in communication with the one end of all the carbons, whilst the other pole may be put into connection with each series of carbons in the different lamps, having separate conductors.

The system of placing the lamp into the circuit may be effected in two ways, namely, either by placing one series of lamps united by a metallic wire in such a way that the current traverses all the carbons, the conductor of one pole being in communication with the first lamp and the conductor of the other pole in communication with the last lamp, or by subdividing the current—that is to say, the current of one pole is subdivided from one point and conducts the current by separate conductors to each lamp. The current of the other pole subdivided in the same way meets the current of the first pole in each lamp.

Having now described my said invention and the mode in
4408 which it may be carried out, I would observe, in conclusion, that I claim as the invention secured to me by the foregoing specification of letters patent—

First. Placing the carbons which are to be lighted on insulators in order that the metallic conductors of the electric current may not be used as supports, and to allow the said carbons a little space to move about in the hollow of the insulators, as hereinbefore described.

Second. Effecting the contact of the carbons with the metal by introducing the metal wire into the carbon and not by fixing or attaching the same outwardly to the carbon.

Third. Connecting the principal conductors with the wire introduced into the thick end of the carbon, and which are exposed to the heat in the lamp by hinges or fastenings of metal, which leave them a little space to move about, substantially as hereinbefore described.

Fourth. Producing nitrogen gas by rarifying the air in the globe by means of the lighted carbons by the electric current and transforming the remainder of oxygen into oxide of carbon by employing an hydraulic closing and valves through which the heated air would escape and which would not al-ow the outward air to introduce itself again into the lamp, all substantially as hereinbefore set forth.

Fifth. Introducing massive pieces or pieces in the shape of tubes closed at one end into the globe in order to retain a certain
4409 length of the globe indispensable for the closing and which at the same time afford the means of having the least possible air in the globe, substantially as set forth.

Sixth. The employment of an automatic mechanism for the passage of the electric current from the one carbon to the other in case of accident or breakage of one of the carbons in the lamp, substantially as hereinbefore described and shown.

In witness whereof I, the said Stephen Alexandrovitch Kosloff, have hereunto set my hand and seal this 13th day of August, in the year of our Lord one thousand eight hundred and seventy-five.

STEPHAN ALEXANDROVITCH KOSLOFF. [L. S.]

Signed by the within-named Stephan Alexandrovitch Kosloff, in my presence, this 1–13 day of August, 1875.

FRED'K LESLIE,
British Vice-consul.

[CONSULATE SEAL.]

4410 DEF'T'S EX. JENSEN (KONN'S) ENGLISH PATENT NO. 970 OF 1875. Mar. 13, '89. W. T. F., N. P. & S. E.

(Second edition.)

[British coat of arms.]

A. D. 1875, 16th March. No. 970.

Specification of Peter Jensen.

Electric light apparatus.

London: Published and sold at the patent office sale branch, 38 Cursitor street, Chancery lane, E. C. 1886. Price, 8d.

4411 (Second edition.)

A. D. 1875, 16th March. No. 970.

Electric Light Apparatus.

Letters patent to Peter Jensen, of Chancery lane, London, for the invention of "improvements in the construction of electric light apparatus." A communication from abroad by Stanislas Vikentievitch Konn, of St. Petersburg, in the Empire of Russia.

Dated the 16th March, 1875.

Provisional specification left by the said Peter Jensen at the office of the commissioners of patents with his petition on the 16th March, 1875.

I Peter Jensen of Chancery lane London do hereby declare the nature of the said invention for "improvements in the construction of electric light apparatus" (a communication to me from abroad by Stanislas Vikentievitch Konn of St. Petersburg in the Empire of Russia) to be as follows:

Onto a metallic base piece a metallic socket is screwed air-tight; the socket has a stuffing box with vulcanized India-rubber
4412 packing and with a gland, which receives an upright glass cylinder closed at the top. Inside this glass cylinder there are two upright copper conductors covered with glass tubing; one of these conductors is movable up and down in a metallic socket fastened to the aforesaid metallic base piece; the other conductor passes air-tight through the base piece which here is fitted above and below with a gland having an insulated horngum lining, the space between the two glands being filled with unvulcanized India-rubber washers. Under the aforesaid base piece there is a closed hollow metallic chamber, in which copper conducting connection is made between the bottom of the last named conductor, and an insulated binding screw in connection with the positive pole of an electric current, at its top this conductor is fastened to the bottom plate of the electric light apparatus proper, while the top plate of

the same is fastened to the top of the first named conductor. The electric light apparatus proper consists of say two rows of platina or silver studs resting in recesses in the aforesaid bottom plate, and corresponding rows of platina or silver studs passing through porcelain ferrules in the aforesaid top plate, but the studs all project unequally through the top plate; the bottoms of the upper studs fit into carbon or graphite sockets, and the tops of the lower studs fit in other carbon or graphite sockets; between these upper and lower sockets carbon or graphite stems are inserted in recesses. A contact plate, made of silver or thickly silvered copper is jointed to the first named conductor and rests on the longest of the platina studs; should this carbon stem break, the contact plate drops onto the next longest, and so on. The broken stems falling down are kept from contact with the glass cylinder by a circular metallic shield placed inside the glass cylinder in the lower part of the same. If the last stem should break, the extinguishing of other lamps in connection with the same current is prevented by the falling of the contact piece onto a copper stopping stem which is fastened by a set screw to the bottom plate and passes through a porcelain ferrule in the top plate.

A small tap in connection with the interior of the glass cylinder serves for pumping out the air.

The positive pole current entering the base piece by a binding screw passes through the metallic socket up to the contact piece at
the top thence to the carbon stem in contact therewith which
4413 stem is thereby heated to a white heat; the current then
descends through the conductor connected to the negative
poles.

Should the glass cylinders break, the entering air will cause the rapid *combination* of the carbon stem.

Specification in pursuance of the conditions of the letters patent filed by the said Peter Jensen in the Great Seal Patent Office on the 16th September, 1875.

To all to whom these presents shall come I, Peter Jensen, of Chancery lane, London, send greeting:

Whereas her most excellent majesty Queen Victoria by her letters patent bearing date the sixteenth day of March in the year of our Lord one thousand eight hundred and seventy-five in the thirty-eighth year of her reign did for herself her heirs and successors give and grant unto me the said Peter Jensen her special licence that I the said Peter Jensen my executors administrators and assigns or such others as I the said Peter Jensen my executors, administrators and assigns should at any time agree with and no others from time to time and at all times thereafter during the term therein expressed should and lawfully might make, use, exercise, and vend within the United Kingdom of Great Britain and Ireland, the Channel islands, and Isle of Man, an invention for "improvements in the construction of electric light apparatus" (a communication to me from abroad by Stanislas Vikentievitch

Konn of St. Petersburg in the Empire of Russia) upon the condition (amongst others) that I the said Peter Jensen my executors, or administrators by an instrument in writing under my or their or one of their hands and seals should particularly describe and ascertain the nature of the said invention and in what manner the same was to be performed and cause the same to be filed in the Great Seal Patent Office within six calendar months next and immediately after the date of the said letters patent.

Now know ye that I the said Peter Jensen do hereby declare the
nature of the said invention, and in what manner the same
4414 is to be performed to be particularly described and ascertained in and by the following statement, reference being had to the accompanying drawings and to the letters of reference marked thereon that is to say:—

These improvements will be best understood by reference to the accompanying drawings Fig. 1 and Fig. 2 which are vertical sections at right angles to one another of an electric lamp constructed according to this invention.

On to a metallic base piece *a* a metallic socket *b* is screwed air-tight; the socket *b* has a stuffing box with vulcanized India-rubber packing *d* and with a gland *c* which receives an upright glass cylinder *v* closed at the top. Inside this glass cylinder *v* there are two upright copper conductors *f* and f^1 covered with glass tubing; one of these conductors *f* is movable up and down in a metallic socket *g* fastened to the aforesaid metallic base piece *a* the other conductor f^1 passes air-tight through the base piece *a* which here is fitted above and below with a gland *h* having an insulating horngum lining, the space between the two glands being filled with unvulcanized India-rubber washers *i*. Under the base piece *a* there is a closed hollow metallic chamber above the base or sole plate *l* in which chamber a copper conductor f^{11} forms connection between the bottom of the conductor f^1 and an insulated binding screw *k* in connection with the negative pole of an electric current, at its top this conductor f^1 is fastened to the bottom plate *p* of the electric light apparatus proper, while the top plate of the same *q* is fastened to the top of the first named conductor *f*. The electric light apparatus proper consists of say two rows of platina or silver studs *o* resting in recesses in the aforesaid bottom plate *p* and corresponding rows of platina or silver studs *o* passing through porcelain ferrules in the aforesaid top plate *q* but the studs all project unequally through the top plate *q*; the bottoms of the upper studs *o* fit into carbon or graphite sockets *n* and the tops of the lower studs fit in other carbon or graphite sockets *n*; between these upper and lower sockets carbon or graphite stems *m* are inserted in recesses. A contact plate *r* made of silver or thickly silvered copper is jointed to the first named conductor *f* and rests on the longest of the platina studs *o*; should this carbon stem break, the contact plate *r* drops on to the next longest stud *o* and so on; the broken stems *m* falling down are kept from contact with the
glass cylinder *v* by a circular metallic shield *w* placed inside
4415 the glass cylinder *v* in the lower part of the same. If the last
stem should break, the extinguishing of other lamps in con-

nection with the same current is prevented by the falling of the contact piece *r* or to a copper stopping stem *t* which is fastened by a set screw *u* to the bottom plate *p* and passes through a porcelain ferrule in the top plate.

A small tap *x* in connection with the interior of the glass cylinder serves for pumping out the air.

The positive pole current entering the base piece *a* by a binding screw passes through the metallic socket up to the contact piece *t* at the top thence to the carbon stem *m* in contact therewith which stem is thereby heated to a white heat; the current then descends through the conductor f^1 and f^{11} connected to the negative pole.

Should the glass cylinders break the entering air will cause the rapid combustion of the carbon stem.

And having thus fully described and ascertained the nature of this invention I declare that I claim as the aforesaid improvements in the construction of electric light apparatus:—

Firstly: The mode of mounting the carbon stems substantially as set forth.

Secondly: The guard plate or shield *w* in combination with a closed glass cylinder or chamber *v*.

Thirdly: The contact piece *t* in combination with two or more studs *o* of unequal lengths and with the stopping stem *t*.

And fourthly: The general arrangement of parts substantially as set forth.

In witness whereof I the said Peter Jensen have hereunto set my hand and seal this fifteenth day of September in the year of our Lord one thousand eight hundred and seventy-five.

Electric Lighting Apparatus.

Letters patent to Richard Werdermann, of Princes street, in the county of Surrey, civil engineer, for an invention of "improvements in electric lighting apparatus."

Provisional specification left by the said Richard Werdermann at the office of the commissioners of patents on the 12th December, 1876.

Richard Werdermann, of Princes street, in the county of Surrey, civil engineer. "Improvements in electric lighting apparatus."

My said invention relates to improvements in electric lamps, carbon electrodes for the same, and in other apparatus for the production of electric light.

The carbon electrodes or carbons to be used in connection with the said electric lamps are coated with any suitable material which will protect the same from contact with air and which is volatile when exposed to the intense heat of the voltaic arc—I use by preference calcined magnesia, sulphate of magnesia, borax, sulphate of lime and other substances or bodies which in burning emit a great amount of light.

The principal advantages of such coating of the carbons are the following namely. First. The flame produced by the burning of the carbons which diminishes considerably the intensity of the light by covering the same is reduced to a minimum. Second. By excluding the air from contact with the carbons the heating of the electrodes is partly p-evented. Third. The coating material which is volatilised as the carbons are consumed produces a greater amount of light and reduces the resistance of the circuit

My invention relates partly to an electric lamp not designed to be used in connection with reflectors or holophotes

The carbon electrodes are supported in the required proximity to each other and are automatically adjusted in proportion to their combustion in the following manner that is to say. The carbon pieces are curved so as to form portions of a circle. One of these pieces is secured in a fixed arm or bar and the other is secured in an arm or beam pivoted to the said fixed bar. This pivoted 4419 arm is provided with a balance weight preferably containing sand or liquid which escapes and diminishes the weight, or with an arrangement of clockwork which regulates the action of the said arm or beam and always keeps the carbon points the proper distance apart—Or I may employ electro magnets or other suitable means for automatically regulating the distance of the carbon points from each other during their combustion.

Another part of my invention relates to carbon electrodes to be used without any lamps or regulator as follows, that is to say

Two concentric hollow cylinders of carbon are insulated from each other by any suitable insulating material which when exposed to the heat of the voltaic arc will be volatilized. The inner side of the inside carbon and the outer side of the outside carbon electrode are equally covered with the insulating material. A powerful current of air will pass through the hollow space as through a chimney and will accelerate the combustion of the carbon and of the insulating material. The said inner cylinder instead of being hollow may be solid The outer cylinder is about one inch shorter or longer than the inner one; both are fixed by screws in a holder consisting of two insulated metal cylinders which are connected with the two poles of the electric current generator.

Instead of using carbon cylinders rods of carbon of square, or oblong section may be placed parallel as set forth in the specification of my former letters patent, dated April 24th A. D. 1874 No 1438. It is advantageous to make the negative electrode only half as thick as the positive one, a very uniform consumption of the carbon being thereby obtained.

When the light is not required to illuminate in all directions but when it is desirable to obtain a very powerful point of light I place a rod of carbon in front of a plate of carbon parallel with and insulated from the same by mica or other suitable material.

(Here follows diagram marked p. 4420.)

4421 Specification in pursuance of the conditions of the letters patent filed by the said Richard Werdermann in the Great Seal Patent Office on the 12th June, 1877.

Richard Werdermann, of Princes street, in the county of Surrey, civil engineer. "Improvements in electric lighting apparatus."

My said invention relates to improvements in electric lamps and in carbon electrodes for the same and in other apparatus for the production of electric light.

Description of the Drawing.

Figure 1 is a longitudinal section and

Figure 2 is an end view of a carbon electrode covered or coated according to my invention as hereinafter described.

Figure 3 is a side elevation of an electric lamp constructed according to my invention.

Figure 4 is a longitudinal section and

Figure 5 a transverse section illustrating my improvements in carbon electrodes.

Figure 5^a is a transverse section shewing a modification of the same

Figures 6. 7. 8. 9 are similar views illustrating other modifications of this part of my invention.

Figure 10 shows in transverse section various forms of my improved carbons or carbon electrodes

Figure 11 is a perspective view illustrating a further modification in the construction of my carbon electrodes

Like letters indicate the same parts throughout the drawing

The improved carbon electrodes or carbons *a* to be used in connection with the said electric lamps are coated as shewn at a^1 figures 1 and 2 with any suitable material which will protect the same from contact with air and which is volatile when exposed to the intense heat of the voltaic arc. I use by preference either separately or two or more of them in combination the following materials, namely, calcined magnesia, sulphate of magnesia, borax, boracic acid, sulphate of lime, fire-clay, glass, alumina, or other substances or bodies which in burning emit a great amount of light

The principal advantages of this coating of the carbons are the following namely

1. The flame ordinarily produced by the burning of the carbons and which diminishes considerably the intensity of the light by covering or enveloping the same is reduced to a minimum.
2. By excluding the air from contact with the carbons the heating of the electrodes is partly prevented
3. The coating material which is volatilized as the carbons are consumed produces a greater amount of light and reduces the resistance of the circuit

The electric lamps constructed according to my invention are not designed to be used in connection with reflectors or holophotes. In these lamps the carbon electrodes or carbons are supported in the required proximity to each other and are automatically adjusted in proportion to their combustion in the following manner that is to say. The carbon pieces *a* are so curved as shown in figure 3 as to form portions of a circle. One of these pieces is secured in a fixed support *b* and the other piece is secured in an arm or beam *c* pivoted to the said fixed support. This pivoted arm may be provided with a balance weight preferably containing sand or liquid which escapes and diminishes the weight. But I prefer to provide the said apparatus with an arrangement of clockwork at *d*

which regulates the action of the arm or beam c and always keeps
the carbon points a the proper distance apart. Or I may employ
electro-magnets or other suitable means for automatically
4422 regulating the distance of the carbon points from each other
during their combustion.

My improved carbon electrodes to be used without any lamp or regulator are constructed as follows that is to say.

In figures 4 and 5 I have shewn two concentric hollow carbon cylinders a a^2 insulated from each other by any suitable insulating material as shewn at f and which when exposed to the heat of the voltaic arc will be volatilized. The inner side of the inside carbon cylinder a and the outer side of the outside carbon cylinder a^2 may be equally covered with the insulating material. A powerful current of air will pass through the hollow space g as through a chimney and will accelerate the combustion of the carbon and of the insulating material. The said inner cylinder instead of being hollow may be solid as shewn in figure 5^a. The outer cylinder of these electrodes is about one inch shorter than the inner one as shewn at a^3. Both cylinders are fixed by a screw h in a holder i. I prefer to use a holder consisting of two insulated metal cylinders j, k which are connected with the two poles of the electric current generator as shewn in figure 4.

Instead of using carbon cylinders, rods of carbon of square, oblong, or other suitable section may be placed side by side parallel with each other as set forth in the specification of my former letters patent dated 24th April A D 1874 No. 1438

Figures 6 and 7 shew one of my improved electrodes formed of flat bars or rods a of carbon insulated at f and suspended in the holder i. In figures 8 and 9 I have shown one of the said electrodes consisting of flat rods a secured together by clips l. Various sectional forms of my improved carbon rods are shewn at e figure 10.

When a continuous electric current is used it is advantageous to make the negative electrode only half as thick as the positive one, a very uniform consumption of the carbon being thereby obtained

When the light is not required to illuminate in all directions but when it is desirable to obtain a very powerful point of light I place a rod a of carbon in front of a plate of carbon a^4 parallel with and insulated from the said plate by mica or other suitable material as shewn at m figure 11.

Having thus fully described my said invention and the manner of performing the same I wish it understood that I claim for the purposes above specified.

First—The coating of carbons or carbon-electrodes with metallic oxides or salts for the purposes specified.

Second—The coating of carbons or carbon-electrodes with borax or with boracic acid mixed with, or in which are dissolved, metallic oxides, salts, or other suitable material, as above set forth.

Third—In an electric light or lamp the curved carbons arranged in the manner above specified

Fourth—In the construction of carbons or carbon-electrodes the carbon cylinders placed one within the other or side by side and parallel with each other as above set forth

Fifth—The modification of my invention in which I place the carbon or carbons in front of a carbon plate as above set forth.

Sixth—The employment of mica as an insulating material for carbons used for the production of electric light as above set forth.

In witness whereof I the said Richard Werdermann have hereunto set my hand and seal this twelfth day of June in the year of our Lord one thousand eight hundred and seventy-seven.

4423 Def't's Exhibit English Patent No. 4905 of 1876. W. T. F., S. E.

A. D. 1876, 19th December. No. 4905.

Apparatus for Producing Electric Light, &c.

Letters patent to Samuel Alfred Varley, of Hertford, in the county of Hertford, telegraphic engineer, for the invention of "improvements in apparatus for producing the electric light, parts of which invention are applicable to other purposes."

Sealed the 23rd March, 1877, and dated the 19th December, 1876.

Provisional specification left by the said Samuel Alfred Varley at the office of the commissioner of patents on the 19th December, 1876.

Samuel Alfred Varley, of Hatfield, in the county of Hertford, telegraphic engineer, "improvements in apparatus for producing the electric light, parts of which invention are applicable to other purposes."

This invention is an improvement on previous inventions for which provisional protection was granted to myself in conjunction with Cornelius Varley, bearing date the 24th day of December, 1866, No. 3394, but which was not proceeded with and which was continued by a new application and for which letters patent were granted, bearing date the 15th day of June, 1867, No. 1755.

4424 In the before-mentioned provisional specification a method was described which may be said to have marked a new era in the construction of dynamo-electric machines used for producing the electric light.

Nearly all the subsequent machines which have been designed for this purpose depending for their action upon the principle first described in the provisional specification before referred to, which consisted in making electricity and magnetism developed by the expenditure of mechanical force to act and react on one another in the machine itself in such way as to develop a greatly increased amount of both these forces, the consumption of force giving motion to the machine increasing and having relation to the increased amount of magnetism and electricity produced.

The nature of my present improvement will be rendered more clear by a brief reference to the machine described in the provisional specification hereinbefore referred to, No. 3394, 1866.

The machine therein described consisted of a number of soft-iron cores or bobbins wrapped with insulated wire and mounted on an axle, by means of which they were revolved and to which was attached a reversing com-utator. These bobbins revolved between opposite poles of soft-iron magnets, which were also wrapped 4425 with insulated wire. The soft-iron magnets were so arranged that they presented north and south poles alternately and opposite to one another, and the bobbins, when revolved, were magn*a*tised first in one direction and then in the other, positive and negative electric currents being developed in the insulated wire of the bobbins alternately at each reversal of the magnetic polarity.

The commutator closed the electrical circuit through the insulated wire of the bobbins and the soft-iron magnets, the electricity passing round the soft-iron magnets in the direction to increase their magnetic polarity, which increased polarity reacted upon the bobbins, developing an increased amount of electricity.

Just previous to the reversal of the magnetic polarity the commutator connected the ends of the insulated wires both of the magnets and the bobbins together, and immediately afterwards the commutator reversed the ends of the insulated convolutions of the bobbins relatively to those of the soft-iron magnets and put them again in circuit with one another, so that the electricity now produced by the reversal of the magnetic polarity of the bobbins passed relatively to the magnets the same way as before and maintained their polarity always in one direction.

The capability of the machine just described and of all 4426 others of this class is limited to a considerable extent, from the fact that the force consumed in giving motion to the machine is being converted into magnetism and electricity at the same time. Not only is the magnetism produced less proportionately as electricity is being developed, but force is also wasted.

The electricity produced when the magnetic polarity is reversed neutralizes and lowers the magnetic potential of the bobbins; the consequence of this is when the next reversal takes place and the magnetic potential previously acquired becomes converted into electrical force the electricity produced is less than it would have been had the magnetic potential just previous to the reversal been higher.

My improvement consists in separating the development of the electrical and magnetic forces to a considerable extent, obtaining thereby a greatly increased magnetic potential in the bobbins, which at a later stage becomes converted into electricity of a correspondingly high potential. I effect this by what may be described as splitting up the bobbins; I divide the bobbins into groups, each group having nearly the same relation to the soft-iron magnets as one bobbin in my previous invention; in other words, the alternations of north and south poles between which the bobbins revolve correspond to the number of groups and not to the actual number of bobbins, so that if the machine has 6 groups of 4427 bobbins and each group consists of three bobbins there will be 6 pairs of soft-iron magnets presenting alternate north and south poles instead of eighteen, as would have been the case in my former invention.

The number of bobbins in each groop may be 2, 3, 4, or more. The number of commutators employed may correspond to the number of bobbins forming a group or they may be increased in number, and when electricity of a very high potential is desired the commutators may be increased to the same number as the bobbins.

I now proceed to describe what takes place in one of my improved machines when set in motion, and which for simplicity of description I will suppose to consist of two pairs of soft-iron magnets only and two groups of bobbins, each group consisting of three bobbins.

The first or advancing bobbin of the group when its magnetism is reversed by passing from between the poles of the magnets into those of opposite polarity develops electricity throughout the circuit after passing onward a certain determined distance. When all or a greater part of the electricity has been developed this bobbin is by the action of the commutator cut out of the circuit and receives magnetism only. A little further on the connections relatively to the electrical circuit are reversed, and this bobbin is then again thrown into the circuit. The polarity of the second and fol- 4428 lowing bobbins is now reversed, and the electricity developed thereby passes through the insulated wire of the first bobbin, which is now included in the electrical circuit, and raises its magnetic potential to a very high degree. The first bobbin now passes between the magnetic poles of the opposite polarity, and the high magnetic potential previously acquired develops a corresponding equivalent of electricity. In the same way as the electricity developed in the second bobbin raises the magnetic potential of the first one so does the electricity developed in each following bobbin raise the magnetic potential of the one preceding it.

What I have just described as taking place in the bobbin of one group is also taking place at the same time in the second group, the only difference being that the electricity developed in the bobbins of the one is opposite to that which is being developed in the corresponding bobbins of the other. The insulated wires of the bobbins of the two groups are, however, so connected that the electricity developed in both flows round the soft-iron magnets and through the electrical circuit in the same direction.

By my improved arrangement just described not only do I obtain a higher magnetic and consequently a higher electrical potential than could be obtained from any former inventions, but as the reversal of the bobbin connections takes place when they are receiv-

ing magnetism only and before the reversal of their mag-
4429 netic polarity the whole of the electricity which is produced
at the time of the reversal passes through the electrical circuit.

In my previous invention hereinbefore referred to and in all machines of this class a certain amount of loss occurs both of the magnetic and electrical forces when the insulated wires of the magnets and the bobbins are short-circuited, just previous to the magnetic polarity of the bobbins and during the time the reversal of the connections is being made.

I now proceed to describe the construction of the commutator of a machine having three bobbins to each group.

The ends of the insulated wires of the bobbins are connected to metal discs mounted on the axle of the machine, but electrically insulated from it and also from one another. There are usually three discs to each commutator, two of these discs being employed for changing the connections and one for cutting out the bobbins from the electric circuit.

When the number of commutators correspond to the number of bobbins forming a group the ends of the insulated wire of the bobbin of each of the groups are joined side by side and connected to their respective discs of the commutators. For example, if the machine consists of six groups, then the ends of the insulated wire of
the leading bobbins of each of the groups are joined side by
4430 side and connected to one commutator. The ends of the sec-
ond and following bobbins of each of the groups are joined in the same way together and connected to the second commutator, and the third and last bobbin of each of the groups are connected to one another and to the third commutator.

The springs which rest against the said commutators are so connected as to form a continuous electrical circuit from one to the other throughout the metal discs of the commutators.

The changing of the connections and the cutting out the bobbins from the electrical circuit at regular intervals is effected by dividing or cutting away portions of the discs, the number of divisions having relation to the number of groups in the machine; or, in other words, to the number of changes in the connections which have to be made in each revolution.

The inward motion of the springs which press against the periphery of the commutators is limited by stops of insulating material, so as to prevent the springs following and making contact with the metal discs when a space or a division is opposite to the springs.

By cutting away at regular intervals more or less of the metal discs all the necessary adjustments for reversing and cutting out the bobbins from the electrical circuit at determined positions can be effected.

The object of the commutator is simply to make the necessary
changes in the connections at regular intervals, and its con-
4431 struction admits of modifications.

The iron cores or bobbins may be made of soft iron and split on one side to prevent the development of electrical currents in the body of the iron, or they may be made of a bundle of iron wires or of sheet iron rolled up upon itself.

In some cases to prevent more completely the development of electricity at those periods when I desire magnetism only to be produced I wrap the bobbins with two insulated wires in the reverse direction, and at the time when the bobbins are cut out of the electrical circuit by a modification in the construction of the commutator the ends of the two insulated wires are connected together for a short interval, the effect of which is to more completely neutralize the development of electricity.

Part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used to produce the electric light. There are several well known ways of doing this, but the method I prefer is to wrap the soft-iron magnets with two insulated wires, one having a larger resistence than the other. The circuit of larger resistence is always closed and the circuit of less resistence is used for the electric light.

4432 When the electric light is being produced the greater portion of electricity passes through the circuit of less resistence, which I term the "electric light circuit," maintaining the magnetism of the magnets and producing the light; when the electric light circuit is open from any cause the electricity passes through the circuit of greater resistence only and maintains the magnetism of the magnets.

The electric light is produced by closing the "electric light circuit" through a carbon rod which rests on the periphery of a disc of carbon, usually bevelled on the edge; this disc may be made of what is termed "gas carbon" and which is deposited on the side of the retorts in the process of making coal gas, or they may be made of what is technically termed "moulded carbon."

Motion is given to the carbon disc. The carbon rod rests loosely on the disc, and the contact being imperfect the electric circuit is completed by an electric arc being formed, and a similar effect is produced as when carbon conductors are brought into contact and separated a short distance from one another.

In some cases I construct the carbon disc of segmental pieces of carbon, separating each segment with a suitable non-conducting substance. An electric arc is then formed when the carbon rod is passing over the space occupied by the non-conducting
4433 material.

When a solid carbon disc is used a slight joggling action may be communicated to the carbon rod by any of the well-known methods to insure actual separation. Two carbon rods may also be employed instead of one, the circuit being completed through the one to the carbon disc and through it to the second carbon rod.

I prefer to give rotation to the carbon disc by means of the electric force generated by the machine itself, and so avoid having to depend upon more or less complicated mechanism, which has to be wound up.

I communicate motion in the following way: Hollow helices of insulated wire are arranged end to end, each helix being separated by a space from one another. In these spaces iron discs, mounted on a soft iron spindle (which passes through the helices and runs in suitable bearings), move.

The iron discs are divided into teeth on their outer periphery, and the helices are encased with iron tubes or shells, divided at both ends into teeth, corresponding in number with those cut in the iron discs.

The insulated wire composing the helices is connected to the insulated wire surrounding the soft-iron magnets of the ma-
4434 chine and is usually inserted in the circuit of greater resistance.

When the machine is set in motion the soft-iron cylinder in the centre of the helices becomes pow-fully magnetic, and the teeth of the discs and those of the shells mutually attract one another, giving motion to the iron discs. There is a commutator attached to the soft-iron cylinder which closes and opens the electric circuit through the helices in succession, and the discs are arranged so that their teeth break joints one with the other.

When the machine is in action the helix in the electric circuit renders the portion of the iron cylinder enclosed by its magnetic, and the teeth of the iron discs are attracted by the teeth of the iron shell covering this helix. When the teeth of the disc, moved by magnetic attraction, are almost opposite the teeth of the shell the commutator closes the electric circuit through the 2nd helix and opens it with respect to the one previously polarized. The discs are now moved another step forward. In this way, with a suitable number of helices and divided discs, the electric circuit being closed and opened through the helices in succession, a rotary motion is given to the cylinder, which gives motion to the carbon disc.

The helices are wrapped with two wires, joined together
4435 at one end and insulated at the other. These wires are
wrapped in opposite directions. The electricity which gives motion to the discs passes through one of these wires only, say, for distinction, No. "1;" No. "2" being disconnected at one end, the commutator, just before it opens the circuit of the helix electrically polarized, connects the end of No. "2" to No. "1."

The secondary or extra current, as it is sometimes termed, which is generated when the circuit is opened, now passes into No. "2," which is wrapped in the opposite direction to No. "1," and the demagnetization of the part of the iron cylinder previously magnetized is very rapidly effected in consequence.

In order to ascertain the amount of electric force which is being produced at any time, I attach to the machine an electric gauge which I construct in the following way: I wrap a hollow bobbin, which may be made of brass, with a number of convolutions of soft-iron wire; in the center of this a permanent magnet is mounted in pivots, care being taken that the pivot holes are placed truly in the center so that the poles of the magnet may be as nearly as possible at an equal distance from the iron wire, whatever position the magnet may be in. Circular or segmental coils, usually 4436 made of insulated copper ribbon, are mounted above and below the poles of the magnet, allowing space sufficient for the magnets to pass freely between.

An index or pointer, moving over a divided scale, is connected by a spring to the upper pivot of the magnet and retains the magnet in the center of the circular coils when the machine is not in action.

The circular coils are placed in the electric light circuit and when the machine is in action the magnet is deflected. The index is then turned round until the tension of the spring is sufficient to bring the magnets back again into the center of the coils. The distance traveled by the index to effect this indicates the amount of electric force which is being developed.

Malleable cast iron may be used for the magnets in place of soft iron. Common cast iron may also be used, and permanent magnets may in some cases be substituted with advantage for the soft-iron magnets, but the coercitive force or the power of permanent magnets to resist depolarization is limited, and the development of electricity when the machine is in motion drives back the magnatism, temporarily depolarizing them to some extent, and, consequently, renders them less effective. To neutralize this effect when I use permanent magnets, I prefer to arm them with soft-iron 4437 poles, which I wrap with insulated wire. The electricity developed by the machine is made to pass through this insulated wire and develops sufficient magnetism to neutralize the depolarizing effect before referred to.

Those parts of my invention by which the electricity which produces the light is developed are applicable for nearly all purposes where electricity in large quantities is required.

The high electrical potential which can be readily obtained by my invention renders it, for example, very suitable for the production of ozone, as well as other purposes where electrical currents of high tension are wanted.

The electric gauge used in my said invention and the method of obtaining rotary motion are also applicable to electric currents obtained by chemical action or thermo-electric sources.

Specification in pursuance of the conditions of the letters patent filed by the said Samuel Alfred Varley in the Great Seal Patent Office on the 19th June, 1877.

Samuel Alfred Varley, of Hatfield, in the county of Hertford, telegraphic engineer, "improvements in apparatus for producing the electric light, parts of which invention are applicable to other purposes."

This invention is an improvement on a previous invention 4438 for which provisional protection was granted to myself in conjunction with Cornelius Varley, bearing date the 24th day of December, 1866, No. 3394, but which was not proceeded with, and which invention was made the subject of a second application and — which letters patent were granted to us, bearing date the 15th day of June, 1867, No. 1755.

In the before-mentioned provisional specification a method was described which may be said to have marked a new era in the construction of dynamo-electric machines used for producing the electric light.

Nearly all the subsequent machines which have been designed for this purpose depend for their action on the princip*al* first described in the provisional specification above referred to. This principle as set forth in the said specification consists in causing electricity and magnetism developed by the expenditure of mechanical force to act and react on one another in the machine itself in such a way as to develop a greatly increased amount of both these forces. Such increased amount of magnetism and electricity, as is well understood, involves an increase in the consumption of mechanical force for giving motion to the machine.

The nature of my present improvement will be rendered more clear by a brief reference to the machine described in the provisional specification hereinbefore referred to, No. 339,466.

4439 The machine therein described consisted of a number of soft-iron cores or bobbins wrapped with insulated wire and mounted on an axle, by means of which they were revolved, and to which was attached a reversing commutator. These bobbins revolved between opposite poles of soft-iron magnets, which were also wrapped with insulated wire. The soft-iron magnets were so arranged that they presented north and south poles alternately and opposite to one another, and the bobbins when revolved were magnetized first in one direction and then in the other, positive and negative electric currents being developed in the insulated wires of the bobbins alternately at each reversal of the magnetic polarity.

The commutator closed the electrical circuit through the insulated wire of the bobbins and the soft-iron magnets, the electricity passing round the magnets in their direction to increase their magnetic polarity, which increased polarity reacted upon the bobbins, developing an increased amount of electricity.

Just previous to the reversal of the magnetic polarity the commutator connected the ends of the insulated wires both of the magnets and the bobbins together, and immediately afterwards the commutator reversed the ends of the insulated convolutions of the bobbins relatively to those of the soft-iron magnets and put
4440 them again in circuit, one with another, so that the electricity
now produced by the reversal of the magnetic polarity of the bobbins passed relatively to the magnets the same way as before, and maintained their polarity always in one direction.

The capability of the machine just described and of others of its class as heretofore constructed is limited to a considerable extent, because the force consumed in giving motion to the machine is being converted into magnetism and electricity at the same time, and the magnetism produced is less proportionately as electricity is developed.

The electricity produced when the magnetic polarity is reversed partially neutralizes the magnetism of the bobbins. The consequence of this is that when the next reversal takes place and the magnetism previously acquired thus becomes converted into electrical force the electricity produced is less than it would have been had the magnetism been greater just previous to the reversal.

My improvement consists in separating the development of the electrical and magnetic forces to a considerable extent, obtaining thereby greatly increased magnetic potential in the bobbins, which at a later stage becomes converted into electricty of a correspondingly high potential. I effect this by what may be described as "splitting up" the bobbins—that is to say, I divide the bobbins into groups, each group having nearly the same relation 4441 to the soft-iron magnets as one bobbin had to the soft-iron magnets in my previous machine—that is, in a machine according to the former invention above referred to. In other words, the alternations of north and south poles, between which the bobbins revolve, correspond in my improved machine to the number of groups and not as in my old machine to the actual number of bobbins, so that if the machine has six groups of bobbins and each group consists of three bobbins there will be six pairs of soft-iron magnets presenting alternate north and south poles instead of eighteen, as would have been the case in my old machine.

The number of bobbins in each group may be 2, 3, 4, or more. The number of commutators employed may correspond to the number of bobbins forming a group or they may be increased in number, and when electricity of a very high potential is desired the commutators may be increased to the same number as the bobbins.

I now proceed to describe what takes place in one of my improved machines when set in motion, and which for simplicity of description I will suppose to consist of two pairs of soft-iron magnets only and two groups of bobbins, each group consisting of three bobbins:

The first or advancing bobbin of the group, when its magnetism is reversed by passing from between the poles of the magnets into those of opposite polarity, develops electricity throughout 4442 the circuit after passing onward a certain determined distance; when all or the greater part of the electricity has been developed this bobbin is by the action of the commutator cut out of the circuit and receives magnetism only. A little further on the connections relatively to the electrical circuit are reversed, and this bobbin is then again thrown into the circuit. The electricity developed in the bobbin of the group whose magnetic polarity is next reversed passes through the insulated wire of the first bobbin and raises its magnetic potential to a very high degree. The first bobbin then passes between the magnetic poles of the opposite polarity, and the high magnetic potential previously acquired develops a corresponding equivalent of electricity and raises the magnetic potential of the bobbin following it. In this way the magnetic potential of each of the bobbins is raised to a high degree just before the reversal of its polarity takes place.

What I have just described as taking place in the bobbins of one group is also taking place at the same time in the other group, the only difference being that the electricity developed in the bobbins of the one group is opposite to that which is being developed in the corresponding bobbins of the other. The insulated wires of the bobbins of the two groups are, however, so connected that the electricity developed in both flows round the soft-iron magnets and through the electrical circuit in the same direction.

4443 By my improved arrangement just described not only do I obtain a higher magnetic and consequently a higher electrical potential than could be obtained in my old machine, but, as the reversal of the bobbin connections takes place when they are receiving magnetism only and before the reversal of their magnetic polarity, the whole of the electricity which is produced at the time of the reversal passes through the electrical circuit.

Although for simplicity of description I have above referred to the use of only two groups of bobbins, in practice three or more groups may be used with advantage, the number depending upon the requirements of each particular application.

In my old machine hereinbefore referred to and in other machines of this class a certain amount of loss occurs, both of the magnetic and electrical forces, when the insulated wires of the magnets and the bobbins are short circuited, just previous to the reversal of the magnetic polarity of the bobbins and during the time the reversal of the connections is being made.

I now proceed to describe the construction of the commutators of a machine having three bobbins to each group:

The ends of the insulated wires of the bobbins are connected to metal discs mounted on the axle of the machine, but electrically insulated from it, and also from one another. There may be 4444 three discs to each commutator, two of these discs being employed for charging the connections, and one for cutting out the bobbins from the electrical circuit.

When the number of commutators corresponds to the number of bobbins forming a group the ends of the insulated wires of the bobbins of each of the groups are joined side by side and connected to their respective discs of the commutators; for example, if the machine consists of six groups, then the ends of the insulated wires of the leading bobbins of each of the groups may be joined side by side and connected to one commutator. The ends of the second and following bobbins of each of the groups may be joined in the same way together and connected to the second commutator, and the third and last bobbin of each of the groups may be connected to one another and to the third commutator.

The springs which rest against the commutators are so connected as to form a continuous electrical circuit from one to the other through the metal discs of the commutators.

The changing of the connections and the cutting out of the bobbins from the electrical circuit at regular intervals is effected by dividing or cutting away portions of the discs, the number of divisions having relation to the number of changes which have to be made in the connections during each revolution.

The inward motion of the springs which press against the
4445 peripheries of the commutators is limited by stops of in-
sulating material so as to prevent the spring following and making contact with the metal discs when a space or a division is opposite to the springs.

By cutting away at regular intervals more or less of the metal discs, all the necessary adjustments for reversing the cutting out the bobbins from the electrical circuit at determined positions can be effected.

The object of the commutator is simply to make the necessary changes in the connections at regular intervals, and its construction admits of modification.

The iron cores or bobbins may be made of soft iron and split on one side to prevent the development of electric currents in the body of the iron, or they may be made of bundles of iron wires or of sheet iron rolled up upon itself.

Part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used to produce the electric light. There are several well-known ways of doing this, but the method I prefer is to wrap the soft-iron magnets with two insulated wires, one having a larger resistance than the other. The circuit of larger resistance is always closed and the circuit of less resistance is used for the electric
light.

4446 When the electric light is being produced the greater por-
tion of electricity passes through the circuit of less resistance, which I term the "electric light circuit," maintaining the magnetism of the magnets and producing the light. When the electric light circuit is opened from any cause the electricity developed passes through the circuit of greater resistance only and maintains the magnetism of the magnets.

The electric light is produced by closing the "electric light circuit" through a carbon rod which rests on the periphery of a disc of carbon, usually bevelled on the edge. This disc may be made of what is termed "gas carbon," and which is deposited on the sides of the retorts in the process of making coal gas or they may be made of what is technically termed "moulded carbon."

Motion is given to the carbon disc. The carbon rod rests loosely on the disc, making imperfect contact, and the electric circuit is completed by the formation of an electric arc, a similar effect being produced as when carbon conductors are brought into contact and separated a short distance from one another.

In some cases I construct the carbon disc of segmental pieces of carbon, separating each segment with a suitable non-conducting substance. An electric arc is then formed when the carbon rod is pass-
ing over the space occupied by the non-conducting material.

4447 When a solid carbon disc is used a slight joggling action
may be communicated to the carbon rod by any of the well-known methods to insure actual separation. Two carbon rods may

also be employed instead of one, the circuit being completed through the one to the carbon disc and through it to the second carbon rod.

I prefer to give rotation to the carbon disc by means of the electric force generated by the machine itself and so avoid having to depend upon more or less complicated mechanism which has to be wound up.

I communicate motion in the following way: Hollow helices of insulated wire are arranged end to end, each helix being separated by a space from its neighbors; in these spaces move iron discs, which are mounted on a soft-iron spindle that passes through the helices and runs in suitable bearings.

The iron discs are formed with teeth on their outer peripheries, and the helices are encased with iron tubes or shells formed at both ends, with teeth corresponding in number with those on the iron discs.

The insulated wire composing the helices is connected to the insulated wire surrounding the soft-iron magnets of the machine, and is usually inserted in the circuit of greater resistance.

When the machine is set in motion the soft-iron cylinders in
4448 the centres of the helices become powerfully magnetic, and the
teeth of the discs and those of the shells mutually attract one
another, giving motion to the iron discs. There are commutators which close and open the electric circuit through the helices in succession, and the discs are arranged so that their teeth "break joint" or alternate one with the other, as hereinafter described.

When the machine is in action the helix in the electric circuit renders the portion of the iron cylinder enclosed by it magnetic, and the teeth of the iron discs are attracted by the teeth of the iron shell covering this helix. When the teeth of the discs, moved by magnetic attraction, are almost opposite the teeth of the shell a commutator closes the electric circuit through *the electric circuit through* the second helix and opens it with respect to the one previously polarized. The discs are now moved another step forward. In this way, with a suitable number of helices and divided discs, the electric circuit being closed and opened through the helices in succession, a rotary motion is given to the cylinder which gives motion to the carbon disc.

Each of the helices is wrapped with two wires joined together at one end and insulated at the other. These wires are wrapped in opposite directions. The electricity which gives motion to the discs passes through one of these wires only, say, for distinction, "No. 1,"
the other ("No. 2") being disconnected at one end. The com-
4449 mutator just before they open the circuit of the helix elec-
trically polarized connects the end of "No. 2" to the end of "No. 1."

The secondary current, or "extra current," as it is sometimes termed, which is generated when the circuit is opened, now passes into "No. 2," which is wrapped in the opposite direction to "No. 1," and the demagnetization of the part of the iron cylinder previously magnetized is very rapidly effected in consequence.

In order to ascertain the amount of electric force which is being produced at any time, I attach to the machine an electric gauge, which I construct in the following way: I wrap a hollow bobbin, which may be made of brass, with a number of convolutions of soft-iron wire; in the centre of this a permanent magnet is mounted on pivots, care being taken -at the pivot holes are placed truly at the centre, so that the poles of the magnet may be as nearly as possible at an equal distance from the iron wire, whatever position the magnet may be in. Circular or segmental coils, usually made of insulated copper ribbon, are mounted above and below the poles of the magnet, allowing sufficient space for the magnet to pass freely between the coils.

An index or pointer moving over a divided scale is connected by a spring to the upper pivot of the magnet, and when the machine is not in action retains the magnet in the centre of the circular coils. 4450

The circular coils are placed in the electric light circuit, and when the machine is in action the magnet is deflected. The index may be then turned round until the torsion of the spring is sufficient to bring the magnet back again into the centre of the coils, or the divided scale may be moved round, which is practically the same thing. The distance travelled by the index to effect this indicates the amount of electric force which is being developed.

In constructing the machines malleable cast iron may be used for the magnets in place of soft iron. Common cast iron may also be used, and permanent magnets may in some cases be substituted with advantage for the soft-iron magnets; but the coercitive force or the power of permanent magnets to resist depolarization is limited, and the development of electricity when the machine is in motion drives back the magnetism, temporarily depolarizing the magnets to some extent, and consequently renders them less effective. To counteract this action when I use permanent magnets I prefer to arm them with soft-iron poles, which I wrap with insulated wire. The electricity developed by the machine is made to pass through this insulated wire and develops sufficient magnetism to neutralize the depolarizing effect before referred to.

4451 Those parts of my invention by which the electricity which produces the light is developed are applicable for nearly all purposes where electricity in large quantities is required.

The high electrical potential which can be readily obtained by my invention renders it, for example, very suitable for the production of ozone, as well as for other purposes where electrical currents of high tension are wanted.

My method of obtaining motion is also applicable to electric currents obtained by chemical action or from thermo-electric sources.

Description of the Drawings.

Sheets 1 and 2 shew the apparatus by which the electrical force is produced.

Sheet 3 shows the apparatus by which the light is obtained and illustrates the way in which the electrical force developed by the machine is measured.

Fig. 1 is a general view of a machine, having four groups of revolving bobbins and three bobbins in each group. Fig. 2 is an end view of the same.

Fig. 3 is an end view, with parts of the machine removed to show how the bobbins revolve over the magnets.

Fig. 4 is a side view of the bobbins removed from the machine, shewing the way in which they are mounted on the axle. Fig. 5 is an end view of the same.

Fig. 6 is an end view of the bobbins, shewing the connections.

Fig. 7 is a side view of the commutator removed from the
4452 machine and shewing its general construction. Fig. 8 is a
sectional view of the same, shewing how the different parts are connected.

Fig. 9 is an end view of the commutator.

Fig. 10 is a sectional view, shewing the construction of parts of the commutator.

Fig. 11 (sheet 2) is a side view and Fig. 12 is an end view, shewing the general construction of a machine having two groups of bobbins only and three bobbins in each group, in which the magnets are arranged in line with the bobbins. The commutator is shown separately in Fig. 17 (sheet 3).

Fig. 13 (sheet 3) is a side view and Fig. 14 an end view of parts of a machine having two groups of bobbins with eight bobbins in each group and shows the form in which I prefer to make the electro-magnets when the construction of the machine admits of it. A sectional and an end view of the iron cores used for these magnets is shewn in Figs. 15 and 16, sheet 3.

Figs. 20 to 25 shew the construction of the apparatus for giving motion to the carbon disc used for producing the electric light.

Fig. 26 is a sectional view of the electric gauge, and Fig. 27 is a top view of the same with parts removed to shew the construction more clearly.

A A (Figs. 1 and 2) are two uprights, usually made of gun metal or other suitable non-magnetic substance, to which are attached the
iron blocks B, more clearly shown in Figs. 2 and 3, and
4453 which form extensions of the poles of the electro-magnets.
C are the electro-magnets attached to the iron blocks B. D is an axle which carries the bobbins E^1 E^2 E^3 F^1 F^2 F^3 G^1 G^2 G^3 H^1 H^2 H^3. I is a pulley attached to the axle by means of which motion is communicated to the machine. I^x is a pulley revolving loosely on the axle, onto which the band is shifted when it is desired to stop the machine. J J are bearings in which the axle runs. K is a cradle in which the bobbins lie. This cradle is attached to the axle and the bobbins are kept in their places by lashing them together by a cord or in any other suitable way. L are the commutators attached to but electrically insulated from the axle. M M^x are contact springs which rest on the commutator discs. When the machines are constructed with a large number of bobbins in each group the extensions of the magnet poles B, as shewn in Figs. 13

and 14, may be made of continuous circles instead of segmental pieces of iron, as the loss of magnetism arising from the opposite magnetic poles being connected by a bridge of iron is in such cases comparatively small.

The way in which the commutators are connected together is
shewn in Fig. 17 (sheet 3), which represents the commutators of a
machine having two groups of bobbins and three bobbins in each
group. The arrangement consists of nine metal discs, divided into
three sets, electrically connected together as indicated by the
4454 dotted diagonal lines; portions of the discs are cut away, as
shown in Fig. 18, which is an end view of one set. L^x L^1
are discs connected to the ends of the insulated wires of the bobbins.
L^2 are the discs through which the circuit is completed when the
bobbins are receiving magnetism only. M and M^x are the contact
springs which press against the metallic discs of the commutators.
L^3 L^4 are metallic discs mounted on but insulated from the axle
D against which contact springs M rest. These are connected to a
divided metallic ring, L^5 L^6, which is mounted on the axle, but insulated from it. An end view of this divided ring is shown in Fig.
19. When electricity in one direction only is required the circuit
is closed through the dotted lines M^2 M^{x2}; when alternate positive
and negative currents are desired the circuit is closed through M^{x2}
M^{x3}.

In Fig. 2 the bobbins E^1 F^1 G^1 H^1 are passing from between the
magnetic poles of one name into those of opposite polarity and are
developing electricity. I term this position of the bobbins "No. 1
position." The bobbins E^2 F^2 G^2 H^2 are disconnected from the
electrical circuit and are acquiring magnetism or magnetic potential
only. I term this "No. 2" position. The bobbins E^3 F^3 G^3 H^3 are
in what I term "No. 3" position—that is, the position where they
are again put into the electrical circuit, the ends of the insulated
wires of the bobbins relative to the general circuit being, however,
reversed to what they were when in "No. 1" position.

4455 The electricity developed in the insulated wires of the
bobbins in "No. 1" position passes through the bobbin in
"No. 3" position, through the insulated wire of the electro-magnets
and through the whole of the electrical circuit, magnetizing the
electro-magnets and increasing the magnetic potential of all the
bobbins in "No. 3" positions. The next reversal takes place during the passage of the bobbins from "No. 3" position to the succeeding "No. 1" position, the bobbins in "No. 2" position passing
on to "No. 3" position and having their magnetic potential raised,
as before described, by the bobbins which are now passing on to
"No. 1" position. In this way the magnetic potential of each of
the bobbins in its passage from "No. 2" position onwards until just
before it reaches the succeeding "No. 1" position is raised to a high
degree, and the magnetic potential thus acquired becomes converted
into electricity during the passage of the bobbin into "No. 1" position and onwards until it reaches "No. 2" position.

To avoid confusion the connections between the magnets, bobbins, and commutators are indicated only generally in the draw-

ings, but their arrangement will be generally understood by electricians from the description given, aided by reference to Figs. 17^{A},
which are theoretical diagrams, showing each of the bobbins
4456 of a single group in the three positions hereinbefore referred
to as "No. 1," "No. 2," and "No. 3."

N (Figs. 20 and 21) is a carbon disc mounted on the axle O, to which are attached the soft-iron cylinders P, with discs or flanges P^x, divided into teeth on their outer peripheries. The iron cylinders revolve in the helices of insulated wire. Q_x p are soft-iron shells surrounding the helices Q. The faces of these shells are divided into teeth corresponding to those of the iron discs. p^x q are helices of insulated wire, which are usually placed over the iron shells to further increase the development of magnetism.

The diagram-atic view, Fig. 22, shews the alternate positions of the teeth of the iron discs and shells. R R^1 are the commutator wheels electrically insulated from one another, and also from the axle. The teeth of these wheels "break joint" one with the other—that is to say, the teeth of one wheel are opposite the spaces between the teeth of the other wheel, as shown in Fig. 21. These wheels alternately close the circuit through the helices when the axle is rotated. r r^1 r^2 r^3 are the demagnetizing commutators, each of which is composed of two divided wheels, the teeth of which "break joint" with one another, the teeth of the one wheel being opposite the spaces between the teeth of the other wheel, as indicated in
Fig. 21. These wheels are insulated from the axle and from one
4457 another. S S^x S^1 S^2 S^3 S^4 are contact springs. S^x S^3 are in
electrical contact with each other. S^1 and S^2 are also electrically connected. S^x is in permanent electrical contact with R, and S^1 is always in contact with R^1. One end of the two insulated wires of which each helix Q q is composed is connected with the axle. The other ends of what I have termed for distinction the "No. 1" wires of the two helices are connected to R and R^1, and the other ends of the "No. 2" wires are connected to r^1 r^2. The electrical circuit is closed through the contact springs S S^4, and the current passes from the axle through the helices alternately and out at S, or *vice versa.*

The circuit is represented in Fig. 20 as closed through the "No. 1" wire of the helix connected to the communtator wheel R, and the Nos. "1" and "2" wires of the helix connected to R^1 are represented as connected together by the demagnetizing commutator r^2.

In Fig. 20 the rotary apparatus is represented as constructed with two hollow helices and revolving cylinders, but it will work better if constructed with three or more helices.

T, Fig. 23, is a carbon rod attached to the lever U and resting by gravity on the carbon block N.

The dotted lines V V, Fig. 26, represent the convolutions of iron
wire of the electrical gauge which insulate the magnets in-
4458 side from external magnetism. W are the circular coils. X
are the magnets working over the surfaces of and between the coils. X^x is an axle to which the magnets are attached. Y^1 is a torsion spring, one end of which is attached to the axle X^x and the

other end to the circle Z, whose surface has degrees marked on it. Z^1 is a handle by means of which the circle Z can be turned round. Y^1 is a pointer attached to the axle X^x and which is deflected when the circuit is closed through the coils of the electrical gauge. Y^x is a fixed pointer which shows the number of degrees *and* divided circle Z has been moved in bringing back the pointer Y^1 to zero and which measures the amount of force exerted by the current on the magnets.

The dotted lines and circles, Fig. 27, shew how the electrical gauge can be rendered much more sensitive to electric currents by increasing the number of coils and magnets as indicated by the dotted lines.

Having described the nature of my said invention and explained the mode of carrying the same into practical effect, I desire to have it understood that save and except as hereinafter mentioned I do not intend to claim any of the mechanical or electrical parts of the apparatus hereinbefore shewn and described when taken
4459 separately and apart from the combination or application
thereof in manner and for the purposes hereinbefore described, but what I consider to be novel and original and therefore claim as secured to me by the hereinbefore in part recited letters patent is—

First. The method hereinabove described of obtaining a high degree of "magnetic potential" in the bobbins by causing the insulated wires of the bobbins at certain determined positions to be cut out of and disconnected from the electric circuit, and whilst so disconnected to acquire magnetism only, and further increasing such magnetism by causing electricity developed in other parts of the machine to pass through the insulating wires of the said bobbins after they have been again put into the electric circuit, but before their magnetic polarity is reversed, the high "magnetic potential" so acquired being converted into electricity at the next reversal of the magnetic polarity of the said bobbins, as described.

Secondly. The method hereinbefore described of obtaining rotary motion by the use of iron discs provided with teeth in conjunction with iron shells or tubes also provided with teeth, the said discs being attached to or forming parts of iron cylinders, which are mounted on a common axle and revolve in helices of insu-
4460 lated wire, which helices by means of commutators are ren-
dered alternately active and inactive, and magnetize in succession the enclosed iron cylinders and shells, the said cylinders and shells being rapidly demagnetized in the manner described.

In witness whereof I, the said Samuel Alfred Varley, have hereunto set my hand and seal this nineteenth day of June, in the year of our Lord one thousand eight hundred and seventy-seven.

S. ALFRED VARLEY. [L. S.]

4461 Def't's Ex. Edison English Patent No. 2402 of 1879.

Specification of Thomas Alva Edison.

Electric lights and apparatus for developing electric currents, &c.

London: Published and sold at the patent office sale branch, 38 Cursitor street, Chancery lane, E. C. 1886. Price 1s. 1d.

4462 (Fourth edition.)

A. D. 1879, 17th June. No. 2402.

Electric Lights and Apparatus for Developing Electric Currents, &c.

Letters patent to Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician, for an invention of "improvement in electric lights and in apparatus for developing electric currents and regulating the action of the same."

Provisional specification left by the said Thomas Alva Edison at the office of the commissioners of patents on the 17th June, 1879.

Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician. "Improvement in electric lights and in apparatus for developing electric currents and regulating the action of the same."

I have ascertained that when wires or sheets of platina, iridium or other metallic conductors of electricity, which fuse at a high temperature are exposed to a high temperature, near their melting point in air for several hours by passing a current of electricity through them and then are allowed to cool, the metal is found to be ruptured, and under the microscope there is revealed myriads of cracks in every direction, many of which are seen to reach nearly to the centre of the wire. I have also discovered that contrary to the received notion, platinum, and iridium alloy loses weight when exposed to the heat of a candle, that even heated air causes it to lose weight, that the loss is so great that it tinges a hydrogen flame green, and under the influence of an electric current and at a yellow white heat the loss is very great. After a time the metal falls to pieces, hence wire or sheets of platinum, or platinum or iridium alloy as now known in commerce are useless for giving light by incandescence.

First: Because its loss of weight makes it expensive and unreliable and causes the burner to be rapidly destroyed.

Second: Because its electrical resistance changes by loss in weight

and its light giving power by the cracks, or ruptures, the melting point being determined by the weakest spot where the greatest difference of potential of the electric current is present which causes this point to be brought to a higher heat than the rest of the surface of the wire; again as it is essential to obtain a steady light
4463 the platinum burner must be screened from the air, and when thus screened, by being placed in a glass vessel, the glass soon becomes coated with a black deposit of platinum.

A platinum spiral brought to incandescence under these conditions may be made to give a light of three standard candles, when near its melting point, and when the radiating surface is $\frac{3}{16}$ of an inch, but this amount of light will be rapidly reduced as before described.

From my researches and experiments I am led to believe that the cause of the rupturing of the metal when brought to incandescence, is due to the action of the gases contained in the pores of the metal. These gases are probably compressed within the pores during the rolling or drawing of the sheet or wire.

These gases, or air, when subjected to high heats are greatly expanded and rupture the metal and it cannot be driven out by slowly heating the metal.

I have also discovered that the loss of weight and apparent vola*ta*lization of the metal is due to the action of the air or gases against the highly heated surface. Having thus ascertained the cause of fracture and loss of weight I have conducted experiments to obviate these defects and have succeeded by the following method. A spiral of platinum wire is placed in a glass bulb, with its ends passing through and sealed in the glass, and the air exhausted from the bulb by a Sprengel pump, until the discharge from a three-inch induction coil, will not pass between two subsid*a*ary wires in the bulb, the ends of which are four millimetres apart; the wires of the spiral are then connected to a magneto-electric machine or battery whose current can be controlled by the addition of resistance. Sufficient current is allowed to pass through the wire, to bring it to about 150° Fahrenheit it is allowed to remain at this temperature for 10 or 15 minutes while thus heated, the air or gases in the pores of the metal is expelled by the action of the heat and the expansion of the gases which tend to pass outward in consequence of the vacuum. While this air or gases is passing out of the metal, the mercury pump is kept continuously working. After the expiration of about 15 minutes the current passing through the metal is to be augmented so that its temperature will be about 300 degrees Fahrenheit and it is allowed to remain at this temperature for another 10 or 15 minutes. If the mercury pump be worked continuously and the temperature of the spiral raised at intervals of 10 or 15 minutes, until it attains to vivid incandescence, and the bulb be then sealed, the metallic wire is then in a state heretofore unknown for it may have its temperature raised, to the most dazzling incandescence emitting a light of 25 standard candles.

Whereas before the treatment, the same spiral would only emit a light equal to three candles, before attaining the melting point.

The wires subjected to the process of freeing them from air and gases, are found after the process, to have a polish exceeding that of silver, and obtainable by no other means, no cracks can be seen even after the spiral has been raised suddenly to incandescence many times by the current, and no volat*a*lization takes place as there is no deposit upon the glass bulb, nor does a delicate balance show any loss of weight in the spiral after burning for many hours continuously, because the spiral is in a vacuum, that is so nearly perfect that the action of the gaseous molecules is reduced to the minimum and were it possible to obtain an absolute vacuum, there would be no loss whatsoever and the total loss after a year's use, would scarcely be noticed. I have further discovered that if an alloy of platinum and iridium or even platinum be coated with the oxide of magnesium, in the manner hereafter stated, and subjected to the vacuum process described that combination takes place between the metal, and the oxide, giving the former remarkable properties. With a spiral having a radiating surface of $\frac{3}{16}$ of an inch, light equal to that given by 40 standard candles may be obtained, whereas the same spiral not passed through my process, would melt before giving a light of 4 candles.

The effect of the oxide of magnesia is to harden the wire to a surprising extent and render it more refractory. A spiral spring made of the wire is as elastic and springy when at dazzling incandescence as when cold.

4464 I have found that chemically pure iron and nickel, drawn in wires and subjected to the vacuum process may be made to give a light equal to that of platinum in the open air.

Carbon sticks may be also freed from air, in this manner and be brought to a temperature, that the carbon becomes pasty and if then allowed to cool is very homogeneous and hard rods or plates made of mixtures of finely divided conducting and non-conducting materials may thus be freed from air. It is also obvious that the metal might be heated by subjecting the containing bulb to a considerable temperature, but this only partially frees the wire from its air or gases.

I will now describe the form of burner or lamp which I employ.

To operate several hundred electric lights practically each equal to an ordinary gas jet, upon one circuit, it is essential for many reasons both on the score of economy, facility and reliability to place them all in multiple arc, and to prevent the combined resistance of several hundred lamps from falling to such a low point, as to require main conductors of immense dimensions, with low resistance, and generating machines of corresponding character, it is essential to reverse the present and almost universal practice of using lamps which have but one or two ohms resistance and construct lamps which shall have when giving their proper light a resistance of several hundred ohms, because the more lamps there are in circuit, the less will be the resistance. I have ascertained by experiment that the loss of energy is in proportion to the extent of the radiating surface, independent of the resistance of the conductor, hence we have 1,000 lamps each of $\frac{1}{4}$ of an inch radiating surface and each of

1 ohm resistance, or 1,000 lamps having the same radiating surface and 1,000 ohms resistance each, the loss of energy from each lamp when giving each a light of 15 candles will be nearly the same, but the combined resistance of the 1 ohm lamps will be $\frac{1}{1000}$ of an ohm requiring an enormous main conductor, whereas the combined resistance of the 1,000 ohms lamp will be 1 ohm requiring a conductor of very moderate dimensions. In practice a resistance of 200 to 300 ohms in the burner will be sufficient.

Again with lamps of low resistance the lamp connections and leading wires must be large to prevent great loss of energy by resistance, the leading wires from the main conductors, are large, expensive, and bulky to handle, the low resistance of the burner, or incandescent conductor requires large terminals to convey the current and these offer by their conduction a medium for the rapid dissipation of energy without producing any effect whereas with a lamp of high resistance all these objections are obviated.

My burner consists of a bobbin composed of an infusible oxide, such as oxide of calcium, cerium, zirconium magnesium freed from silica and turned in a lathe from sticks moulded by hydraulic pressure, in a manner hereinafter set forth.

These wires serve to hold the bobbin in the centre of the sealed glass vacuum bulb, and at the same time serve as conductors of the electric current to the wire coiled upon the bobbin.

The two platinum wires are first passed through small tubes of glass which are melted around the wires. The burner is introduced into the bulb and the wires are passed out through the sides of the narrow neck leading from the bulb and the glass is melted around them to prevent leakage, the glass of the neck being melted to the small glass tube around the wires.

Before the burner is permanently sealed at the neck, the air pump is connected therewith and the wire upon the bobbin is subjected to the vacuum process heretofore described and the electric current is used to produce incandescence for about one hour to heat the bobbin and thereby expel the air and gases, after which the bulb is permanently sealed by melting the glass of the neck, and it is ready to be used as a lamp.

The method which I adopt for regulating the light radiated from the burner, consists in a small rotating magnet provided with a governor which serves to open the lamp circuit when the 4465 strength of the current is greater than is necessary to produce the proper light in the bobbin. This apparatus is very reliable and although the current supplied is not perfectly continuous, the total energy passing to the lamp in one hour is nearly the same, no matter what the strength of the current may be. The magnets are so arranged that the continuous metallic circuit cannot be broken by the commutator of the revolving magnet and the extra current produced by the reversal of the current in the revolving magnet is short circuited by the fixed magnet, hence the sparks which would occur at the break points of the governor are prevented.

The rotating magnet is upon a vertical shaft supported in suitable bearings, and immediately over the rotating magnet is the fixed magnet, the cause of which are in the path described by the rotating magnet. Upon the shaft is a reversing commutator formed of an insulated ring, the periphery of which is faced with platina, and cut in two parts, one part being connected by a wire to one helix of the revolving magnet, and the other part to the other helix of said magnet, the two helices being connected. Rubbing on this ring are two contact springs which serve to convey the currents to the revolving magnet.

The current passes through the fixed magnet thence through the revolving magnet, the rotation of the magnet being kept up by the reversal of the direction of flow of the currents through the revolving magnet.

When the cores of the revolving magnet are nearest the cores of the fixed magnet the direction of the flow of current is reversed by the action of the commutator springs and commutator and the polarity changed, hence the attraction ceases, but the momentum of the revolving magnet carries said magnet forward and mutual attraction again takes place as the revolving cores approach the stationary cores the current is reversed and the revolution continued.

Connected to the revolving shaft is a governor which consists of two collars connected together by two springs: one collar is secured to the shaft while the other is free to slide thereon.

Upon each spring a weight is secured and the rotation of the shaft causes these to act centrifugally and bow outward the springs and raise the sliding collar upward more or less in proportion to the speed of the shaft.

The sliding collar is made with a groove to receive the end of the circuit opening lever which lever is moved by the rise and fall of the collar. The other end of the lever has an insulated cross bar which is in contact with two circuit breaking springs and serves to disconnect the springs simultaneously from their contact points or blocks when the shaft has reached a certain velocity.

The object of using two springs is to open the circuit at two places simultaneously and thus reduce the spark, which it does in the ratio of the number of simultaneous breaks.

One of the two springs is connected by a wire to one of the commutator springs and the other is connected to the wire leading from the main conductor, or a branch therefrom. This method of breaking the circuit simultaneously in many places is applicable to all kinds of electrical apparatus where large and powerful sparks occur, as for instance if it is desired to transfer electric energy from one point to another by dynamo electric machines operating upon a magneto electric motor to a distant station. If four springs are employed, and the circuit opened at the four places simultaneously the spark will be reduced to $\frac{1}{16}$ of what it would be if it was opened at but one place.

The block to which the two circuit breaking springs are secured is connected to a screw so that said block and springs can be positioned or adjusted with reference to the cross bar on the governor lever.

By turning this screw to the right the block and springs are moved until the cross bar moves the springs away from their contact points or bars and disconnects the lamp from the circuit: the reverse movement places the lamp in circuit, and according to the proximity of the springs to the cross-bar of the governor lever so the amount of current to the burner is regulated. A stop is applied to the screw so that it can be turned only to a determined
4466 point which limits the amount of current passing to the
burner. I prefer that each burner shall give a light equal to 16 candles the burner being capable of giving 35 candle power without fusion.

As there may be a point where the revolving magnet after being at rest will not start when the current is put on, I use an automatic starter which consists of a light lever and thin armature turned edgewise which is attracted by the fixed magnet at the moment the current is put on. The movement of this lever which carries upon its end a click serves to give a sudden motion to the shaft of the revolving magnet by the click engaging in a ra*ck*et or toothed wheel secured to the shaft.

The click after making this movement passes beyond the ratchet and does not come in contact again until the magnet is stopped and the current is broken.

In the specification of my British patent No. 5306 of 1878, I have described the manner of coating the wire with pyroinsulating material. I employ that mode in coating the wire after which a coil of said wire is wound upon one or more li*me* supports and placed in a sealed bulb that is connected to a spengel vacuum apparatus and by gradually increasing the heat of the wire by the gradual rise in the strength of the current as described in the first part of this specification the wire is not only freed from air and rendered more refractory but the oxide is vitrified and shrinks upon the wire from which it cannot be detached.

The coil after passing through this process may be wound upon the lime bobbin of the lamp without breaking the pyroinsulation.

After the bobbin is wound and placed in the final bulb it has any air which may have passed into the oxides expelled by a gradual accession of current in the manner heretofore described and the bulb is then sealed.

The oxides of the alkaline material which are infusible attack the platina to a slight extent and as herewith greater tenacity to it than the oxides which do not attack it such as cerium or zirconium but the compound thus formed renders the wire more refractory.

It is not essential that the oxide should be in the form of a soluble salt as it may be put on the wire directly by mechanically mixing the oxide with water, alcohol, or other liquids, but special devices are requisite to keep the mixture in constant agitation to prevent settling.

It has been found very difficult to mould slender sticks of the oxides enumerated on account of the bending and breaking of the plunger of the mould which owing to the pulverulent nature of most of the oxides must be long and slender.

I have obviated this difficulty by devising a mould and plunger by which pressures to the crushing point of steel may be concentrated upon one quarter of an inch surface.

This apparatus is applicable to the moulding of any substance.

The block that receives the mould is of cast iron with a taper hole in the centre. The mould is made of three pieces and has the same taper as the hole in the block.

The object of the taper and split mould is to allow the pressed piece to be taken out without injury which it would receive were it forced out of the mould endwise.

The plunger is upon the end of a sliding stock and said plunger is only about $\frac{1}{4}$ of an inch long and about $\frac{3}{8}$ of an inch in diameter and it is adapted to pass downwardly into the hole in the centre of the split mould.

After the mould has been filled to the top with the pulverulent oxide a steel washer or punch section is placed upon the oxide and forced into the mould by the plunger. Afterward another punch section is placed upon the first one and forced into the mould in the same manner, thus sections may be added until the desired pressure is obtained without any disarrangement of the apparatus. So powerful is the pressure which may be obtained by this means that cylinders of the oxide of magnesium are rendered semi-transparent.

The cylinder of oxide thus obtained is placed on a lathe and the bobbin turned with a cutting tool without fear of breaking.

The electric generating machine which I propose to use consists of a powerful field magnet between the poles of which rotate an induction bobbin.

The cores of the field magnet are each three feet in length
4467 and about six inches in diameter and wound with a helix of
insulated copper wire having a resistance of about one ohm.

The number of coils and the resistance of the wire may of course be varied to meet various conditions. By the use of large masses of iron I am enabled to reduce the resistance of the magnetic circuit to a very low point and at the same time by reason of this large mass of iron of great magnetic conductivity, the use of a single layer of wire is possible thus obtaining the maximum economy.

The back or bar that connects the two cores of the magnet is of iron and is greater in mass than in the same length of core. The surface of both the back and the end of each core are ground together and are permanently secured by bolts and nuts. By thus employing a large mass of iron for the back and grinding the faces of contact to a point where air suction becomes powerful I reduce the resistance of this point to a minimum and prevent the appearance of free magnetic poles.

There are iron poles bolted to the cores the surfaces being ground together.

Between the two poles there is a circular aperture in which the induction cylinder rotates.

The cylinder may be of wood upon a shaft and at each end of the cylinder there is a wrought iron head.

This cylinder or bobbin is wound with fine wire until the wire is flush with the edge of the iron heads.

Over this cylinder is wound longitudinally the insulated induction wire the ends of which are connected to the commutator. The wire of the parallel induction helix is substantially endless and it is wound with reference to obtaining a continuous current.

The number of parallel coils may be more or less in number but I find the desired object can be obtained by using an even number of parallel coils longitudinally of the cylinder and an odd number of commutator plates.

There are two insulated disks upon the shaft of the field magnet and a metallic brush or spring is in contact with each disk, the line wires are connected to these disks. One end of the wire of the field magnet is connected to one disk and the other end of the wire is connected with one of the commutator brushes, the other commutator brush is connected with the second insulated disk.

The path of the current is through one insulated disk to the field magnet through it to one commutator block then through the induction coil to the opposite block on the commutator and by brush and wire the second insulated disk and thence to the line.

The current will be continuous or nearly so and travel in one direction there will however sometimes be a spark between the commutator bars when the circuit of the parallel induction coil is interrupted but this will be lessened by having the commutator springs bent to rest on more than one commutator bar.

It will be apparent that the shell and parallel induction coil may be revolved if the magnet cylinder remains stationary and I remark that the cylinder supporting the parallel induction coil may be of any suitable material but I prefer vulcanized fibre.

The parts of this machine are not liable to become heated under ordinary circumstances of use, because the wires are not wound one on the other and the atmosphere has an opportunity to circulate.

I however apply a fan in some instances upon the shaft of the field magnet within a case communicating with the internal portions of the machine so as to induce a current of air through the same.

As I have heretofore set forth the maximum economy of illuminating by electricity when using a great number of light giving points is only obtainable by working the resistance in multiple arcs, hence it is also necessary that the generating machines should also be worked in multiple arc.

To work a great number of machines in multiple arc with economy and reliability it is essential that all should have the same electro motive force and that means must be devised to prevent the insulating covering of the induction bobbin of any 4468 machine being burned should the same stop for any reason such as by the breaking of a belt, because if the wire of the bobbin cease to be the seat of an electro motive force the current from the other machines pass through it and tend to produce sufficient heat to destroy the insulation and at the same time cause a loss of available energy.

I prevent any such action by the use of a polarized magnet which prevents the electric circuit being opened by the direction of the flow of the current from the machine when in action tending to hold its tongue strongly against a contact point, but if the machine should stop and cease to be the seat of an electro motive force, a current from the other machines passes through the machine in a contrary direction whereupon the tongue of the polarized magnet is attracted from its contact point and the circuit opened.

Each machine being provided with this apparatus, it is freed from the danger aforementioned.

An ordinary magnet with its armature lever provided with a retractile spring might replace the polarized magnet but the margin for adjustment would be very small.

The resistance of the polarized magnet is made an exceedingly small fraction of the resistance of the machine to prevent loss of energy.

The field magnets of the machine are energized by supplying their helices with electricity from thermo-electric piles.

Compound condensing steam engines are employed at the large central stations to drive the magneto-electric machines and the heat given off from the surface condensers acts upon thermo electric piles to produce an electric current and the same is passed through the field of force helices.

The field magnets may all be connected in multiple arc and the thermo electric piles arranged in the same manner with appliances whereby the strength of all the field may be increased or decreased at pleasure, thus increasing or decreasing the electro motive force of the induction bobbins thus making it easy and convenient by the aid of electro meters at the central stations to counteract the rise and fall in the electro motive force on the main conductors when the maximum and minimum number of lamps may be working.

I will mention that the electro motive force of the machines is analogous to the pressure in the system of gas lighting and at dusk when the lamps are being rapidly connected to the circuit, the electro meter will show a slight drop on the electro motive force or pressure and this may be increased by increasing the speed of the prime mover or increasing the power of the field magnets, the later method is the one I prefer.

The surface condensers which I employ consists of a great number of iron pipes whose surfaces are painted with a thick coating of a non-conducting substance. The pipes after painting are about five inches in diameter.

Over these pipes are slipped rings of the double sulphide of lead and copper. These rings are cast in a mould and both the inner and outer edges are either covered or plated with copper.

The inner copper ring of one disk connects with the outer copper ring of the adjoining disk throughout the entire series of disks.

Owing to the exceedingly low resistance of these disks and the considerable electro motive force which they give between low range of temperature, very powerful currents are obtained and nearly as much energy is thus obtained in the form of an electric current from the waste heat of the engine as can be obtained from the engine itself through the medium of the Faradic machines.

In British letters patent No. 4226 of 1878 granted to me, a method is described and shown for measuring the total energy passing into the house of the consumer during a given period of time, the same consisting of a depositing cell or cells in which the weight of copper deposited by the current gives the indication.

Instead of the cell or cells shown two cells connected by a syphon may be used.

4469 In one cell is a solution of cupric sulphite and a copper electrode and in the other cell sulphuric acid and a copper electrode. No polarization takes place; the liquid of the syphon tube offers the requisite resistance.

The cells are sealed from the air to prevent loss by evaporation.

Any loss by this means may be made good by adding water, the results are nearly independ*a*nt of the strength of the solution.

The central stations are intended to light an area of $\frac{1}{4}$ of a mile in every direction. The method which I propose to adopt for conveying the current from the central station to various points consists in laying double wrought pipes lined with vulcanized rubber known as ebonite side by side under the flagging stones near the edge of the sidewalk. The pipes are to be in 20 feet lengths, the four ends passing into a cast iron box.

The pipes and box are water-tight.

The top of the box which is detachable has its upper surface even or flush with the walk, from the same box small tubes serve to convey wires from the main conductors to the houses of the consumers.

The wires forming the main conductors are small and may either be insulated and laid loosely together or insulated with a thin layer of cotton. In this case each consumers wire will be independent, but the economy is greater when the wires are all in contact, as then when few lamps are in use the resistance of the main conductor is relatively small as compared to the lamps.

The practice of causing the total resistance of the circuit extraneous to the generator to be equal to that of the generator and by which the maximum effect*s* is obtained from the machine, is very wasteful of energy, for by thus arranging the resistance fifty per cent. of the energy is lost in the machine itself, whereas if the exterior resistance is four times greater than the machine, the capacity of the machine to translate energy from one to the other is lessened, but of what is translated owing to the changed conditions 80 per cent may be utilized.

For this reason I so arrange the resistance of the main conductors that they should be but $\frac{1}{10}$ of the total resistance of all the lamps, and the resistance due to the *the* generating machines is kept down by keeping in multiple arc a greater number of machines than is necessary to supply all the lights which may happen to be in circuit at the time.

4470 Specification in pursuance of the conditions of the letters patent filed by the said Thomas Alva Edison in the Great Seal Patent Office on the 17th December, 1879.

Thomas Alva Edison, of Menlo Park, in the State of New Jersey, United States of America, electrician. Improvements in electric lights and in apparatus for developing electric currents and regulating the action of the same.

I have ascertained that when wires or sheets of platina, iridium or other metallic conductors of electricity which fuse at a high temperature are exposed to a high temperature near their melting point in air for several hours by passing a current of electricity through them and then are allowed to cool, the metal is found to be ruptured and under the microscope there is revealed myriads of cracks in every direction many of which are seen to reach nearly to the center of the wire.

I have also discovered that contrary to the received notion, platinum, or platinum and iridium alloy loses weight when exposed to the heat of a candle, that even heated air causes it to lose weight, that the loss is so great that it tinges a hydrogen flame green, and under the influence of an electric current and at a yellow white heat, the loss is very great. After a time the metal falls to pieces, hence wire or sheets of platinum or platinum and iridium alloy as now known in commerce are useless for giving light by incandescence, 1st because its loss of weight makes it expensive and unreliable and causes the burner to be rapidly destroyed. 2nd because its electral resistance changes by loss in weight and its light giving power by the cracks or ruptures, the melting point being determined by the weakest spot where the greatest difference of potential of the electric current is present which causes this point to be brought to a higher heat than the rest of the surface of the wire. Again as it is essential to obtain a steady light the platinum burner must be screened from the air and when thus screened by being placed in a glass vessel, the glass soon becomes coated with a black deposit of platinum. A platinum spiral brought to incandescence under these conditions may be made to give a light of three standard candles when near its melting point and when the radiating surface is $\frac{3}{16}$ of an inch, but this amount of light will be rapidly reduced as before described.

From my researches and experiments I am led to believe that the cause of the rupturing of the metal when brought to incandescence is due to the action of the gases contained in the pores of the metal. These gases are probably compressed within the pores during the rolling or drawing of the sheet or wire. These gases or air when subjected to high heat are greatly expanded and rupture the metal and it cannot be driven out by slowly heating the metal

I have also discovered that the loss of weight and apparent volatilization of the metal is due to the action of the air or gases against the highly heated surface.—Having thus ascertained the cause of fracture and loss of weight I have conducted experiments to obviate these defects and have succeeded by the following method:—

A spiral of platinum wire is placed in a glass bulb with its ends passing through and sealed in the glass and the air exhausted from the bulb by a Sprengel pump until the discharge from a three inch induction coil will not pass between two subsid*u*ary wires in the bulb the ends of which are four millimetres apart: the wires of the spiral are then connected to a magneto electric machine or battery whose current can be controlled by the addition of resistance. Sufficient current is allowed to pass through the wire to bring it to about 150° Fah: it is allowed to remain at this temperature for 10 or 15 minutes. While thus heated the air or gases in the pores of the metal are expelled by the action of the heat and the expansion of the gases which tend to pass outward in consequence of the vacuum.

While the air or the gases are passing out of the metal
4471 the mercury pump is kept continuously working. After the
expiration of about fifteen minutes the current passing through the metal is to be augmented so that its temperature will be about 300° Fahr. and it is allowed to remain at this temperature for another ten or fifteen minutes. If the mercury pump be worked continuously and the temperature of the spiral raised at intervals of ten or fifteen minutes until it attains vivid incandescence and the bulb be then sealed the metallic wire is then in a state heretofore unknown for it may have its temperature raised to the most dazzling incandescence emitting a light of twenty five standard candles, whereas before treatment the same spiral would only emit a light equal to three candles before attaining the melting point.— The wires subjected to the process of freeing them from air and gases are found after the process to have a polish exceeding that of silver and attainable by no other means, no cracks can be seen even after the spiral has been raised suddenly to incandescence many times by the current and no volatilization takes place as there is no deposit upon the glass bulb, nor does a delicate balance show*n* any loss of weight in the spiral even after said spiral has been burning for many hours continuously because the spiral is in a vacuum so nearly perfect that the action of the gaseous molecules is reduced to the minimum and were it possible to obtain an absolute vacuum there would be no loss whatever.

I have further discovered that if an alloy of platinum and iridium or even platinum be coated with the oxide of magnesium in the manner hereafter stated and subjected to the vacuum process described, that combination takes place between the metal and the oxide giving the former remarkable qualities. With a spiral having a radiating surface of $\frac{3}{16}$ of an inch, light equal to that given by forty standard candles may be obtained whereas the same spiral not passed through my process would melt before giving a light of four candles. The effect of the oxide of magnesia is to harden the wire to a surprising extent and render it more refractory.

A spiral spring made of the wire is as elastic and springy when at dazzling incandescence as when cold.

I have found that chemically pure iron and nickel drawn in wires and subjected to the vacuum process may be made to give a light equal to that of platinum in the open air.

Carbon sticks may be also freed from air in this manner and be brought to a temperature that the carbon becomes pasty and if then allowed to cool is very homogeneous and hard. Rods or plates made of mixtures of finely divided conducting and non conducting materials may thus be freed from air.—It is also obvious that the metal might be heated by subjecting the containing bulb to a considerable temperature but this only partially frees the wire from its air or gases.

I will now describe the form of burner or lamp which I employ:—To operate several hundred electric lamps practically, each equal to an ordinary gas jet, upon one circuit, it is essential for many reasons both on the score of economy, facility and reliability, to place them all in multiple arc, and to prevent the combined resistance of several hundred lamps from falling to such a low point as to require main conductors of immense dimensions with low resistance and generating machines of corresponding character, it is essential to reverse the present and almost universal practice of using lamps which shall have but one or two ohms resistance and construct lamps which shall have when giving their proper light, a resistance of several hundred ohms, because the more lamps there are in the circuit the less will be the resistance. I have ascertained by experiment that the loss of energy is in proportion to the extent of the radiating surface independent of the resistance of the conductor, hence we have 1,000 lamps each of $\frac{1}{4}$ of an inch radiating surface, and each of one ohm resistance, or 1,000 lamps having the same radiating surface and 1,000 ohms resistance each, the loss of energy from each lamp when giving each a light of 15 candles will be nearly the same, but the combined resistance of the one ohm lamps will be $\frac{1}{1000}$ of an ohm, requiring an enormous main conductor,
4472 whereas the combined resistance of the 1,000 ohm lamps will be one ohm, requiring a conductor of very moderate dimensions—In practice a resistance of 200 to 300 ohms in the burner will be sufficient—Again with lamps of low resistance the lamp connections and leading wires must be large to prevent great loss of energy by resistance, the leading wires from the main conductors are large expensive and bulky to handle, the low resistance of the burner or incandescent conductor requires large terminals to convey the current and these offer by their conduction a medium for the rapid dissipation of energy without producing any effect, whereas with a lamp of high resistance all these objections are obviated.

My burner *b*, consists of a bobbin composed of an infusible oxide such as oxide of calcium, cerium, zirconium, magnesium, freed from silica and turned in a lathe from sticks molded by hydraulic pressure in a manner hereinafter set forth, and upon this bobbin fine wire of platinum or platinum-iridium alloy is coiled. This bobbin is shown in Fig. 1. It is secured to two platinum wires 1. 2. as in Fig. 2. These wires serve to hold the bobbin in the center of the sealed glass vacuum bulb and at the same time serve as conductors of the electric current to the wire coiled upon the bobbin.—Fig. 3. shows the manner of connecting the wire upon the bobbin to the platina supports. The two platina wires 1. 2. are first passed through a small tube *a*. of glass and the glass melted around the wires: the burner *b* is introduced into the bulb *c*. and the wires 1. & 2. are passed out through the sides of the narrow neck leading from the bulb and the glass is melted around them to prevent leakage; the glass of the neck is melted to the small glass tube *a*. Before the burner is permanently sealed at the neck, the air pump is connected therewith and the wire upon the bobbin is subjected to the vacuum process heretofore described and the electric current is used to produce incandescence for about one hour to heat the bobbin and thereby expel*l* the air and gases after which the bulb is permanently sealed by melting the glass of the neck and it is ready to be used as a lamp as represented in Fig. 4.

The method which I adopt for regulating the light radiated from the burner consists in a small rotating magnet provided with a governor which serves to open the lamp circuit when the strength of the current is greater than is necessary to produce the proper light in the bobbin. This apparatus is very reliable and although the current supplied is not perfectly continuous the total energy passing to the lamp in one hour is nearly the same, no matter what the current strength may be, the magnets being so arranged that the continuous metallic circuit cannot be broken by the commutator of the revolving magnet and the extra current produced by the reversal of the current in the revolving magnet is short circuited by the fixed magnet hence the sparks which would occur at the break-points of the governor are prevented. Referring to Fig. 4. *b*. is the bobbin with the platinum iridium wire which forms the electric lamp. *c* is the sealed glass bulb. *f*. and *g*. are supports to hold the bulb in position; these are insulated from each other.—The platinum wires 1. and 2. from the bulb are connected to these supports.

m. is a box for supporting the lamp and enclosing the governor. *n*. is the back of the fixed magnet consisting of the spools o. o^1. p. p.^{1} are the spools of the revolving magnet: *r*. is the back of the same which is secured permanently to the shaft *q*. upon which is a revolving commutator *s*. This commutator consists of a ring of insulating material whose periphery is faced with platina and cut in two parts, one part being connected by the wire 5. to the magnet p^1. and the other part by the wire 4. to the magnet *p*. The wire 65. connects the two spools *p*. and p^1, together.

Rubbing on this ring are two contact springs s^1. t^1. which serve to convey the currents to the revolving magnet The current passes through the fixed magnet o. o^1. see diagram Fig. 5. thence by wires 4. 5. springs s^1. t^1. through the revolving magnet p. p^1. The rotation of the magnet is kept up by the reversal of the direction of the flow of the currents through the revolving magnet.—When the cores of the revolving magnet are nearest the cores of the fixed magnet, the direction of the current through the former is reversed by the action of the springs s^1. t^1. upon the commutator and
4473 the polarity changed hence the attraction ceases, but the

momentum of the magnet *p*. p^1 carries it forward and mutual attraction again takes place as the revolving cores approach the stationary cores, the current is reversed and the revolution continued.

Connected to the revolving shaft *q*. is the governor which consists of two collars *v*. *w*. connected by springs 6 & 7: the collar *v*. is permanently secured to the shaft while the collar *w*. is free to slide up and down upon it.—Each spring is provided at its center with a weight and these weights act centrifugally to bow outwardly the springs and raise the collar *w*. upwardly more or less in proportion to the speed of revolution. Connected to *w*. by a sleeve is another collar 19. upon the surface of which rests the end of the circuit opening lever *l*. which rises and falls by the action of the governor. A spiral spring l^1. see Fig. 5. on the axis of the lever *l*. serves to keep *l*. in contact with 19. Upon the exetrme end of the lever *l*. is a block 18. in juxtaposition to circuit breaking springs 8 & 9. and serves to disconnect the springs simultaneously from the metallic block 10. when the governor and shaft has reached a certain velocity.—The block 10. is insulated from the frame 11. and serves to keep the circuit closed between the springs.

The current passes by wire 84. to the spring 8. thence across the block 10. to the spring 9. thence to the magnet and lamp by wire 85.

The object of employing two springs is to open the circuit in two places simultaneously and thus reduce the spark which it does in the ratio of the square of the number of simultaneous breaks.—This method of breaking the circuit simultaneously in many places is applicable to all kinds of electrical apparatus where large and powerful sparks occur as for instance if it is desired to transfer electric energy from one point to another by dynamo electric machines. The distant machine which serves to give out the power for driving machinery may be provided with a governor the same as herein shown and the circuit may be opened in several places simultaneously by the action of the governor shown in Fig. 6. *l*. is the lever operated by the governor. 12 and 13. are contact springs which rest upon the bar 43. 14. and 15. are also contact springs which rest on the bar 44. The current passes by wire 84. to spring 12. across the bar 43. to spring 13. thence by wire 45. to spring 14. across bar 44. to spring 15. to wire 85. When the governor reaches a certain velocity, the insulated piece 18. of the lever *l*. comes in contact with all the springs simultaneously and separates them from the bars 43. & 44. thus opening the circuit in four places simutaneously the spark is reduced to $\frac{1}{16}$ of what it would be if a single break was used. Having shown the importance of breaking the circuit simultaneously in many places, I will now describe how the illumination of the burner *b*. may be increased or decreased or stopped entirely.

Referring to Figs. 4. & 5. *t*. is the thumb nut for regulating the speed of the revolving magnet and consequently the amount of energy which passes to the burner. The nut 22. is provided with a slot or groove containing a stationary pin p^2. and into the nut 22. the screw 20. passes and by turning this screw the block 10. may be drawn inwardly or forced outwardly, said block running on two guide pins 23. 24. which prevent the block from turning, thus the block 10. may be made to approach or recede from the lever *l*.

If it is desired to turn off the light and disconnect the lamp altogether from the circuit, the screw is turned to the right until the block 18. separates the springs 8. & 9. from the block 10 and opens the circuit. In this position the circuit is broken and the lamp and magnets are entirely disconnected from the circuit.

If it is desired to have the lamp give light the screw is turned to the left: when the springs 8 & 9. come in contact with the block 10. and close the circuit, the magnets immediately revolve and if the parts are left in such a position that the piece 18. is in close proximity to the springs, the rotation of the magnet will operate the governor and lessen the pressure of 8. and 9. on 10. and hence the speed will be comparatively slow and the electricity passing to the light will be very small and but little light will be given
4474 out, but by causing the block 18. to further recede from 8 &
9. the speed of the magnet will increase and more energy will pass to the lamp in a given time.

By continued turning of the screw 20 a point may be reached where the governor lever *l*. will not separate the springs 8 & 9. from 18; in this case the entire electric energy passes through the bobbin *b*. but in practice limiting stops are applied so that when the screw has been turned a certain distance the further movement will be prevented by the action of the stops, thereby determining the maximum light which the consumer can obtain from the burner. In practice this will be about sixteen candle power, the burner being capable of giving thirty-five candle power without fusion.

As there may be a point where the revolving magnet after being at rest will not start when the current is put on, I use an automatic starter which consists of a light lever and thin armature turned edgewise which is attracted by the fixed magnet at the moment the current is put on. The movement of this lever which carries upon its end a click serves to give a sudden motion to the shaft *q*. by the click engaging in a ratchet or toothed wheel which is secured to it. The click after this movement passes beyond the ratchet and does not come in contact again until the magnet is stopped and the current is broken.

In the specification of my British patent No. 5306 of 1878, I have described the manner of coating the wire with pyroinsulating material: I employ that mode in coating the wire after which a coil of said wire is wound upon one or more bobbins and placed in a sealed bulb and connected to a vacuum apparatus and by gradually increasing the heat of the wire by the gradual rise in the current strength as described in the first part of this specification, the wire is not only freed from air and rendered more refractory but the oxide is vitrified and shrinks upon the wire from which it cannot be detached. The coil after passing through this process may be wound upon the lime bobbin of the lamp without fear of breaking the pyroinsulation. After the bobbin is wound and placed in the final bulb any air which may have passed into the oxides is expelled by a gradual accession of current in the manner heretofore described and the bulb is then sealed. The oxides of the alkaline materials which are infusible attack the platina to a slight extent and adhere with greater tenacity to it than the oxides which do not attack it, such as cerium or zirconium but the compound thus formed renders the wire more refractory.

It is not essential that the oxide should be in the form of a soluble salt as it may be put on the wire directly by mechanically mixing the oxide with water, alcohol or other liquids, but special devices are required to keep the mixture in constant agitation to prevent settling.

It has been found very difficult to mold slender sticks of the oxides spoken of on account of the bending and breaking of the plunger of the mold, which owing to the pulverulent nature of most of the oxides, must be long and slender.

I have obviated this difficulty by devising a mold and plunger by which pressures to the crushing point of steel may be concentrated upon one quarter of an inch surface. This apparatus is applicable to the molding of any substance and it is shown by a vertical section in Fig. 7. Fig. 8, is a plan of the divided mold. a^2. is the plunger; upon the extreme end is the part d^2. which enters the die or mold. This is only about one-quarter of an inch long and about three eighths of an inch in diameter and it is adapted to pass downwardly into the mold.

e^2 is a solid block of cast iron with a taper hole in its center and into this the divided steel mold f^2. is forced; this mold is made of three pieces and has the same taper as the hole in the block e^2. The object of the taper and divided mold is to allow the pressed piece to be taken out without the injury it would receive were it forced out of the mold endwise.—After the mold has been filled to the top with the pulverulent oxide, a steel washer or plunger section h^2. is placed upon the oxide and forced into the mold by the plunger; afterwards another plunger section is placed upon the first one and forced into the mold in the same manner. Thus sections
may be added until the requisite pressure is obtained with-
4475 out any disarrangement of the apparatus. So powerful is
the pressure which may be obtained by this means that cylinders of the oxide of magnesium are rendered semi-transparent.—The cylinder of oxide thus obtained is placed in a lathe and the bobbin turned with a cutting tool without fear of breaking.

The electric generating machine which I propose to use consists of a powerful field magnet between the poles of which rotate an induction bobbin. This apparatus is shown by a vertical section in Fig. 9, and sectional plan Fig. 10. F. is the field magnet the cores of which are about three feet in length and the diameter about six inches wound with a helix of insulated copper wire having a resistance of about one ohm.—The number of coils and the resistance of the wire may of course be varied to meet various conditions.—By the use of large masses of iron I am enabled to reduce the resistance of the magnetic circuit to a very low point and at the same time by reason of this large mass of iron of great magnetic conductivity, the use of a single layer of wire is possible, thus obtaining the maximum economy. a^3. is the back of the magnet and the mass of iron is greater than in the same length of core. The surface of both the back and the end of each core are ground together and are permanently secured by bolts and nuts. By thus employing a large mass of iron for the back and grinding the faces of contact to a point where air suction becomes powerful, I reduce the resistance of this point to a maximum and prevent the appearance of free magnetic poles.—a^4. a^5. are iron poles bolted to the cores, the surfaces being ground together. Between the two poles there is a circular aperture in which the induction cylinder rotates. The cylinder b^3. is preferably of wood upon the shaft b^4, and has wrought iron heads b^5. This cylinder is wound with fine iron wire b^6. until the wire is flush with the edge of the iron heads b^5. Over this cylinder is wound longitudinally the insulated induction wire in sections, the ends of which are connected to the commutator i^4. as in Fig. 11. There are heads e^3. of hard rubber, vulcanite fiber or equivalent material secured to the shaft b^4. see Figs. 16. and 17, outside the heads b^5. and are of larger diameter so that the induction wires e^4. that are wound longitudinally may be kept from contact with the iron helix b^6. or heads b^5. so that the current may not be short circuited even if the insulation of the induction wires e^4. is imperfect.—e^5. is a pulley for driving the machine. e^6. is a loose pulley upon which the belt from the driving shaft is thrown by a shifter when the machine is to be stopped.

d^3. is a switch by means of which the circuit from the Faradic machine may be opened—d^4 and d^5. are the commutator springs. h^3. is a polarized magnet included in the circuit which serves automatically to open the circuit should a reverse current be sent through the machine. The connections are as follows:—From the post i^3. to the commutator i^4 thence through the induction helix e^4. to the opposite side of the commutator and by the brush d^5. to the switch d^3. thence to the tongue of the magnet h^3. if the switch lever is in contact with i^5. thence through the tongue of h^3. to the point i^5. and through the magnet h^3, to the post h^6. The wire upon the field magnet is connected to the clamping posts l^3. and l^4. I will now describe the method of winding the induction cylinder and the direction of the current relative to the commutator brushes.—The wire of the parallel induction helix is substantially endless and it is wound with reference to obtaining a continuous current: the diagram Fig. 11. illustrates the manner of winding the wires; the number of parallel coils may be more or less than that shown, but I find the object desired can be attained the best by using an even number of parallel coils longitudinally of the shaft and an odd number of commutator plates. Starting say from the part b. of the commutator the wire passes to the space 4. on one head e^3. to the same space on the other head, then across the head to the space 11. and to the same space on the other head, then across the head to the space 4. and so on until the spaces 4 and 11 are filled with the

wire and when the last turn in 11. has been laid, the wire is led to
the plate *c.* and then the spaces 2. and 9. are filled and the wire
4476 from 9. led to *d;* then 14, and 7. and a connection made with
e; then 12. and 5. connecting with *f.* then 10. and 3. connecting with *g.* then 8. and 1. connecting with *a.* then 6 and 13. connecting with *b.* the place of beginning.

I wind the wires in such a manner that while the current is continuous and the current flowing through the whole of it, the current will pass by two wires of the induction coil to one commutator plate and then away and will enter by an opposite commutator plate and pass by two wires out into the coil and circulate through the same to the other commutator plate. Suppose the springs to rest upon commutator plates *a.* and *e.* the current will flow towards *a.* from wires 1. and 6. and away from *e.* by wires 12. and 7. By following the arrows it will be found that the entire coil is a complete circuit in which the parallel portions of the wires in the south field of magnetic influence have a current energized in one direction and in the north field in the other direction, thus obtaining the dynamic effect, and there is no break or pulsation of the current, the springs touch one commutator before leaving another.

As I have heretofore set forth the maxim economy of illuminating by electricity when using a great number of light-giving points is only obtainable by working the resistance in multiple arc, hence it is essential that the generating machines should also be worked in multiple arc. To work a great number of machines in multiple-arc with economy and reliability it is essential that all should have the same electro motive force and that means must be devised to prevent injury, by burning, to the insulating covering of the induction coil of any machine, should said machine stop for any reason such as by the breaking of a belt, because if the wire of the induction coil ceases to be the seat of an electro-motive force, the current from the other machines pass through it and tend to produce sufficient heat to destroy the insulation and at the same time cause a loss of available energy.

I prevent any such action by the use of the magnet h^3. Fig. 10. which being polarized is prevented from opening the electric circuit by the direction of the flow of current from the machine when in action, tending to hold its tongue strongly against the contact point i^5. but if the machine should stop and cease to be the seat of an electro-motive force, a current from the other machine tends to pass through the machine in a contrary direction, whereupon the tongue h^3. is detached from the point i^5. and the circuit opened. Each machine being provided with this apparatus is thus freed from the danger described. An ordinary magnet might replace the polarized one and a retractile spring used but the margin for adjustment would be very small.

The resistance of the magnet h^3. is made an exceedingly small fraction of the resistance of the machine to prevent loss of energy.

The field magnets of the machine are energized by supplying them with electricity from thermo electric piles.

Compound condensing steam engines are employed at the large central stations to drive the magneto electric machines and the heat given off by the surface condensers act upon the thermo electric piles to produce an electric current and the same is passed through the field of force helices.

The field magnets may all be arranged in multiple arc and the thermo electric piles arranged in the same manner with appliances whereby the strength of all the field magnets may be increased or decreased at pleasure, thus increasing or decreasing the electro motive force of the induction bobbins, thus making it easy and convenient by the aid of electrometers at the central stations to counteract the rise and fall in the electro motive force on the main conductors when the maximum and minimum number of lamps may be working.

I will mention that the electro-motive force is analogous to the pressure in the system of gas lighting and at dusk when the lamps are rapidly being connected to the circuit, the electrometer will show a slight drop on the electro-motive force or pressure, and this may be increased either by increasing the speed of the prime mover or an increase in the power of the field magnets; the latter method is the one I prefer.

4477 The surface condensers which I employ consist of a great number of iron pipes whose surfaces are painted with a thick coating of a non-conducting substance. The pipes after painting are about five inches in diameter. Over these are slipped rings of the double sulphide of lead and copper. These rings are cast in a mold and both the inner and outer edges are either covered or plated with copper. In Figs. 12. and 13. m^3. is the ring or disk of double sulphide m^4. the copper ring fitted in the hole of m^3. m^5 is a copper ring which fits over the circumference of m^3. to this ring a binding post and strip or wire m^6. is secured, the latter to connect to the next disk. m^7 represents one of the condensing pipes.

m^8. m^9. m^{10} & m^{11} a series of disks arranged to give a current. The inner copper of m^8. connects to the outer copper of m^9 and in this manner to many hundreds of disks. Owing to the exceedingly low resistance of these disks and the considerable electro motive force which they give between low ranges of temperature, very powerful currents are obtained and nearly as much energy obtained in the form of an electrical current from the waste heat of the engine as can be obtained from the engine itself through the medium of the Faradic machines.

The central stations are intended to light an area of $\frac{1}{4}$ of a mile in every direction. The method which I have adopted for conveying the current from the central station to various points, consists in laying double wrought pipes lined with vulcanized rubber known as ebonite, side by side under the flagging stones near the edge of the sidewalk.—The pipes are to be in twenty feet lengths, the four ends passing into a cast iron box.—The pipes and box are water tight. Fig. 14. is a vertical section of one line of pipe and Fig. 15. is a perspective view representing the box and two lines of conductors.

For electric lighting purposes I employ a main conductor M composed of many wires uninsulated from each other but insulated as a whole from the earth by the ebonite coating of the pipe P. but for telegraphic purposes each of the small wires instead of acting as parts of one main conductor are to be insulated from each other by being coated with cotton and afterwards passed through an insulating substance such as resin, tar, paraffine or other non-conductor.

By first putting down pipes P. in sections of say twenty or twenty five feet and boxes B. between the sections, wires may be introduced sufficient for the purpose at the time, and in the future the number of wires may be increased by drawing others through the pipes. The boxes B. allow for introducing or guiding the wires by hand. In practice it will be preferable to employ small pulleys in each box with a stout cord running backward and forward through the line of pipe, for drawing the wire through each section.—The box has a cover *c.* which is bolted to it, and soft rubber, or oiled leather washers are placed between the top and the box to prevent air or water leaking into the box. The inside of the box and cover is to be lined with ebonite or other non-conducting and water proof material. One end of the system of tubes passes into the central station and if the other ends are closed a vacuum may be produced within the whole system of pipes: this will promote the evaporation of any moisture which may have passed into the pipes but the vacuum will only be required periodically. If the two ends pass into central stations warm dry air may be passed through occasionally to prevent dampness.—In the system of electric lighting two lines of pipes are employed on each side of the street but these may be separate and have independent boxes; I prefer that both lines of pipes on each side of the street should be connected to one range of boxes as illustrated in Fig. 15. A small pipe *s.* insulated with rubber is connected at right angles to the main pipes and passes from one of the boxes into the house to be illuminated and carries the conductor which may be made of one or more wires: from the other main conductor another small tube *s.* serves to carry the second wire to the house. These wires entering the house through the meter are carried into various rooms and the electric lamps connected in multiple arc between the two. The wires forming the main conductors are small and as mentioned previously may be uninsulated and laid loosely together or insulated with a thin layer of cotton. In the latter case each consumer's wire would be independent but the economy is greater when the wires are all
4478 in contact as then when few lamps are in use the resistance
of the main conductor is relatively small as compared to the lamps. The practice of causing the total resistance of the circuit extraneous to the generator to be equal to that of the generator almost universally prevails, and by which the maximum effect is obtained is very wasteful of energy, for by thus arranging the resistances fifty per cent. of the energy is lost in the machine itself, whereas if the exterior resistance is four times greater than the machine the capacity of the machine to translate energy from one to the other is lessened, but of what is translated, owing to the

changed conditions, eighty per cent. may be utilized.—For this reason I so arrange the resistance of the main conductors that they should be but one tenth of the total resistance of all the lamps, and the resistance due to the generating machines is kept down by keeping in multiple arc a greater number of machines than is necessary to supply all the lights which may happen to be in circuit at the time.

I claim as my invention

First. The combination with a sealed vacuum chamber made of a glass vessel, of a continuous incandescent conductor wound upon a bobbin of infusible material, substantially as set forth.

Second. The method herein described of preparing metals and metallic conductors for electric lamps or burners, consisting in freeing the metallic conductors of gases in a vacuum and then hermetically sealing the surrounding air tight transparent case, substantially as specified.

Third. In an electric lamp, the combination with a sealed transparent vacuum case of a bobbin of pyroinsulated wire wound upon an infusible substance substantially as specified.

Fourth. In combination with an electric light and the circuits thereof, two electro-magnets one of which is caused to revolve, a governor operated by the speed, and a circuit regulator controlled by the governor, whereby the uniformity of the current passing to the light is maintained, substantially as set forth.

Fifth. In combination with an electric light, an adjustable circuit regulator composed of the insulated springs connected with the circuit wires, a contact block upon which said springs rest, and a governor lever l to regulate the pressure of the contact springs upon the contact block, substantially as set forth.

Sixth. The process of molding sticks of pulverulent material consisting in filling the mold with the material to be compressed and then compressing the mass by successive operations by means of a plunger and plunger sections, substantially as described.

Seventh. The divided mold f^2 and block e^2 in combination with the plunger a^2 and plunger sections h^2 substantially as and for the purposes set forth.

Eighth. The combination in a magneto electric machine of the helix of wire b^6 and the wires e^4 wound and connected to the commutator blocks i^4 as described and forming a parallel induction coil that occupies the space and revolves between the poles of the field magnet, substantially as set forth.

Ninth. The combination in a magneto electric machine of the magnetic cylinder composed of the helix b^6 surrounded by the parallel induction coil e^4 and revolving between the poles of the field magnet, the commutator i^4 springs d^4 and d^5 and circuit connections substantially as set forth.

Tenth. In a magneto electric machine, a parallel induction coil the wires of which are wound substantially as shown in Fig. 11, and commutator connections to the wires whereby the current is taken off from the parallel induction coil at two points in opposite directions, substantially as set forth.

The cylinder b^3 of wood or similar material with the iron heads b^5 and intervening helix of wire b^6 in combination with the disks e^3 of non-conducting material and the induction helix e^4 wound lengthwise and into notches in the edges of the insulating disks, substantially as set forth.

Twelfth. A polarized electro-magnet in the multiple arc circuit of the magneto electric machine for opening the circuit to the machine to which it is connected in case of dera-gement of said machine.

4479 Thirteenth. The thermo-electric piles connected as set forth upon the condensing pipes of an engine in combination with the magneto-electric machine substantially as set forth.

Fourteenth. The combination with the electric conductors M. of metallic tubes lined with hard rubber or similar non-conducting substance, substantially as set forth.

Fifteenth. The metallic tubes lined with non-conducting material such as hard rubber, in combination with metallic boxes B lined with similar material, and uniting the tubes and the conductors passed through such tubes substantially as set forth.

Sixteenth. An induction bobbin nearly surrounded by the poles of the field magnet and the combination therewith of an abnormally large field magnet which shall be in proportion to the size of the pole-pieces as described, for obtaining a powerful electro-motive force in the wires of the revolving bobbin without great loss of energy as set forth.

In witness whereof I have hereunto set my hand and seal this twenty-fifth day of November, A. D. 1879.

MINISTÈRE DU COMMERCE.

Brevets d'Invention.

Mémoire descriptif annexé au brevet d'invention de quinze ans pris, le 18 Décembre, 1872, par la compagnie d'éclairage électrique Lodyguine et Cie et qui lui a été delivré par arrête du Ministre de l'Agriculture et du Commerce, en date de 19 Mars, 1873, pour un mode d'éclairage électrique et les appareils y employés.

Brevet No. 97583.

Le nouveau mode de éclairage électrique que nous avons inventé et que nous exposons ici diffère essentiellement de ceux connus et employés jusqu'a ce jour.

La lumière électrique obtenue à l'aide des appareils actuellement en usage, est due à la translation, de particules incandescentes d'un conducteur à l'autre et à la réaction chimique produite par une température élevée entre ces particules et l'oxygène de l'air ambiant Cette haute température se produit lorsque les bouts des conducteurs se trouvent placés à une certaine distance l'un de l'autre. L'éclat de la lumière obtenue est d'autant plus grand que les corps employés connue conducteurs de l'électricité.

4482 Notre nouveau mode d'éclairage électrique repose sur le propriété que possède le courant d'échauffer et de porter à la température rouge les corps mauvais conducteurs de l'électricité.

La figure (1) du plan, que nous joignons à cet exposé, montre la difference qui existe entre les appareils employés jusqu'à ce jour et ceux dont nous sommes les inventeurs.

A représente les conducteurs d'un appareil ordinaire, *a a* sont les extrémités taillées en point de ces conducteurs. C'est entre ces extrémités que se produit l'arc lumineux.

La figure B représente les conducteurs dans notre nouvel appareil. Il est formé d'un corps mauvais conducteur de l'électricité. C'est la parte qui dans ce conducteur s'échauffe sous l'influence du courant électrique, arrivé à la température rouge et devient par suite lumineuse.

Dans les appareils employés actuellement la production de la lumière électrique est due à la combustion des extrémites des conducteurs qui pour cela même se détériorent promptement et qui doivent être remplacés souvent.

4483 Dans nos nouveaux appareils et d'après notre nouvelle méthode, le conducteur est plongé dans un gas avec lequel il ne reágit pas; il n'est soumis à aucune combustion et cependant il y a production de lumière.

Cette Lumière est obtenue non par une réaction chimique, mais par une action mécanique, par le passage d'un courant électrique d'une grande puissance à travers notre conducteur, qui est alors porté au rouge et devient lumineux.

Il n'est d'ailleurs nullement détérioré par la haute température à laquelle il est soumis, et ne demande pas par conséquent à être renouvelé fréquemment.

Avec les appareils employés actuellement pour produire la lumière électrique, l'on ne peut obtenir par le passage d'un courant que quatre points lumineux. D'après notre méthode et avec nos appareils on peut en obtenir plusieurs milliers. Ainsi, augmentation du nombre des points lumineux obtenus, conservation intégrale des conducteurs, telles sont les différences qui existence entre un éclairage électrique coûteux et un autre très bon marché, celui- là même dont nous sommes les inventeurs.

La lumière obtenue avec les appareils actuels a un tel éclat que la vue peut à peine la supporter. D'après notre nouveau mode
d'éclairage, cet éclat peut être diminué a volonté de 10
4484 à 15 fois, lumière produite par les appareils ordinaires est
inégale et vacillante, inconvénient des plus graves pour la vue.

Au contraire la lumière électrique produite par nos nouveaux appareils peut par son bon marché, par la douceur et la fixité absolue de son éclat rivaliser avec tous les modes d'éclairage actuellement employés.

Afin d'obtenir un courant électrique d'une grande puissance, nous employons les machines électro-magnétiques de Ledda Wilda Nolle et autres beaucoup moins coûteuses que les batteries galvaniques et produisent en outre un courant d'uen intensité bien plus grande.

Les lanternes que nous avons imaginées pour utiliser notre nouveau mode d'éclairage électrique sont représentées par les figures 2 et 3 de la planche ciannexée.

La figure 3, se compose d'un manchon en verre terminé à ses deux extremités par des montures métallique t'' t''', que traversent les conducteurs F^2 F^3 F^4 F^5. Le mauvais conducteurs m' m' communique avec la machine electro-magnetique par un fil metallique f^2. L'autre m'' m'' est mis en communication avex m' m' par le monture t''' même de la lanterne. Le courant amené par le fil
metallique F^2 passe par le conducteur m' m' qu'il porte au
4485 rouge traversé par F^3, la monture t''', arrive par F^4 dans le
conducteur m'' m'' qu'il porte également au rouge et passe
ensuite dans la lanterne suivante par le fil de fer F^5.

La seconde lanterne Fig. 2, se compose comme la première d'un manchon en verre, terminé aussi a ses extremites par des montures metalliques.

Cette lanterne ne possède qu'un seul conducteur m m. Le courant entrant par le conducteur m m qu'il porte au rouge et ressort par le fil de fer F^1.

Les pièces métalliques q et q' (figures 2 et 3) fixées la première par la charnière 1 au couvercle t', la seconde au fil de fer F^2 par la charnière l', serviraîent a intercepter le courant, dans le cas où une ou plusieurs lanternes ne devraient pas être utilisées.

En effet, si F^2 n'est pas mis en communication avec F^5 par la pièce q', le courant forcée de passer par le conducteur m' m' le portera au rouge. Si au contraire la pièce q' se trouve abaissée sur le crochet r', le courant la suivra et sortira par le fil métallique F^5.

En effet la pièce en métal est un meilleur conducteur de l'électricité que les conducteurs m' m', m'' m''.

Il en serait de même pour la lanterne représentée par la
4486 figure 2. Si la piece metallique q fixée à la monture t' par
la charnière l, s'appuie sur la crochet r, le courant ayant à

choisir entre le conducteur m m et la pièce métallique q, qui est un meilleur conducteur de l'électricité, suivra évidemment. Cette dernière m m se trouvant donc plus sur le passage du courant ne sera pas porté au rouge et par suite ne deviendra pas lumineux.

Dans le cas où l'on ne voudrait utiliser aucune des lanternes, il suffirait évidemment d'arrêter le mouvement de la machine électromagnétique.

Les conducteurs m, m', m'', doivent être en coke, en graphite ou toute autre substance qui pourrait servir au même but et qui remplirait les mêmes conditions.

Les lanternes elles-mêmes formées comme nous l'avons dit de manchons en verre n, n'' fermées à leurs extrémités par des montures métallique t, t', t'', t''', forment réservoirs n^2 n^3, qui sont remplis d'azote ou d'un autre gaz inerte et ne pouvant donner lieu à aucune combinaison chimique avec les conducteurs m, m', m''.

Les réservoirs n^2 n^3 peuvent être cylindriques prismatiques ou avoir toute autre forme. Il en est de même des conducteurs m, m', m''. En outre chaque lanterne peut contenir un ou plusieurs de ces conducteurs.

4487 Les lanternes ou reservoirs n^2 n^3 doivent être fermées hermêtiquement. Comme nous l'avons déjà dit les montures sont métalliques. Elles se composent de disques. C'est en outre dans ces rebords que vient s'emboiter le manchon de verre n.

Le fils de fer F, F', F^2 F^5 passent par des ouvertures f, f' f^2 pratiquées dans les montures métalliques t, t', t''.

Dans la lanterne représentée par la figure 3 le fil de fer F^2 se trouve isolé de la monture t'' par un manchon e, en verre ou en toute autre substance isolante.

Complainant's Exhibit Cut of King Lamp

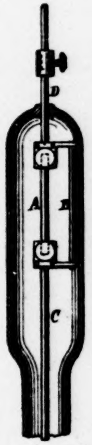

FIG. 45
King's Lamp.

No. 286.
C.E. Light Co.
v.
McK. Light Co. } p. 4489

U. S. Circuit Court,
Western District of Pennsylvania.

Consolidated Electric Light Co.
vs.
McKeesport Light Co.

In Equity.

It is agreed that the above is a correct copy of the Complainant's Exhibit Cut of King Lamp and may be used in place of the original which has been mislaid.

Defendants Solicitor

4490 *Stipulation as to the Omission of Certain Exhibits from the Record on Appeal.*

Circuit Court of the United States, Western District of Pennsylvania.

CONSOLIDATED ELECTRIC LIGHT COMPANY *vs.* MCKEESPORT LIGHT COMPANY. } No. 5, May Term, 1888. In Equity.

It is stipulated by and between the counsel for the respective parties that the following exhibits offered by the defendants in connection with the cross-examination of complainant's witness, Albon Man, need not be filed or printed:

Baldwin-Cheever Telegram, January 6, 1880.
2d Baldwin-Cheever Telegram of January 6, 1880.
Baldwin, Hopkins & Peyton-Cheever Telegram of January 7, 1880.
Baldwin-Cheever Telegram of January 5, 1880.
Cheever-Baldwin Telegram of January 6, 1880.
Baldwin-Cheever Telegram of January 7, 1880.
Horseshoe-Cheever Bill of February 1st, 1880.
Hopkins, Baldwin and Peyton-Cheever Bill.
Baldwin-Cheever Letter of April 27, 1880.
Baldwin-Cheever Letter of April 27, 1880.
Baldwin-Cheever Letter of April 17, 1880.
Pope-Cheever Letter of May 12, 1880.
Baldwin-Man Letter of September 27, 1880.
Dynam*e* Bill.
Accounts and Jay Lease.
Flanagan Agreement, December 16, 1887.
Accounts of Flanagan's Disbursements, December 16, 1887.
Sawyer-Man-Keith Record, April 26, 1888.
Sawyer-Man-Maxim Record, April 26, 1888.
Sawyer-Man-Westen Record, April 26, 1888.
4491 Man-Cheever Letter of December 12, 1880.

It is further stipulated that the copies (attached to the record) of the following exhibits, to wit:

Defendant's Exhibit Baldwin-Wallace Letter of January 8, 1880, and Defendant's Exhibit Memorandum of Agreement of January 8, 1880, being a memorandum signed by Charles A. Cheever and witnessed by William D. Baldwin and dated January 8, 1880, shall be received and filed in lieu of the originals, production of which is hereby waived.

Dated Sept. 24, 1890.

MAGNUS PFLAUM,
Solicitor for Defendant.
THOMAS B. KERR,
Solicitor for Complainant.

Filed Oct. 10, 1890.

4492 Circuit Court of the United States for the Western District of Pennsylvania.

THE CONSOLIDATED ELECTRIC LIGHT COMPANY, Complainants,
vs.
MCKEESPORT LIGHT COMPANY, Defendants.
} On Bill and Final Hearing.

Opinion of the Court.

BRADLEY, *Circuit Justice:*

This is a bill for the alleged infringement of a patent, filed December 8th, 1887, and the patent alleged to be infringed is dated May 12th, 1885, and is for improvements in electric lamps. It was granted upon the application of William E. Sawyer and Albon Man, of New York, to their assignee, the Electro-Dynamic Light Company, and by mesne assignments was transferred to the complainant, whose title commenced in October, 1882, before the patent was issued. The application for the patent was filed January 9th, 1880, and the issue was delayed by various proceedings in the Patent Office, including an interference with an application of Thomas A. Edison, which had been filed a month earlier, to wit, December 11th, 1879. Various defences were set up in the answer, such as anticipation by prior inventions, vagueness of description, want of novelty and utility, undue change of specification 4493 after filing, surreptitious claim of an invention made by Edison, &c. It is conceded that the defence of the suit is conducted by Edison Electric Light Company, a corporation of New York, which sells the lamps complained of as infringements of the patent and is interested as assignee in the patents for electric light formerly owned by "The Edison Electric Light Company" and in the question of interference between Edison and the complainants.

In the specification of the patent sued on, called Sawyer & Man's patent, the invention is described as relating to that class of electric lamps employing an incandescent conductor inclosed in a transparent hermetically sealed vessel or chamber from which oxygen is excluded, and constituting an improvement upon the apparatus shown in a previous patent granted to the same parties (Sawyer and Man) June 18th, 1878, and numbered 205,144.

It is further stated in the specification that the invention relates more especially to the incandescing conductor, its substance, its form, and its combination with the other elements composing the lamp, and that the improvement consists, first, of the combination, in a lamp chamber composed wholly of glass, as described in the said former patent, of an incandescing conductor of carbon made from a vegetable fibrous material, in contradistinction to a similar conductor made from mineral or gas carbon, and also in the form of such conductor combined in lighting circuit within the exhausted chamber of the lamp.

The construction of the lamp is then described, reference being made to the drawings for illustration. The lamp, as described

and shown in the drawings, is a glass cylinder with
4494 rounded top cemented at the bottom to a glass disk or plate
ground to fit closely to the cylinder, and the whole bottom enclosed in a cup filled with wax or suitable cement to prevent, as far as possible, the access of atmospheric air. Two holes are made in the bottom of the lamp for the passage of the wires which convey the electric current into and out of the lamp. The carbon conductor within the glass cylinder is connected by its extremities to these two wires respectively in a mode specified in another patent of Sawyer & Man, dated December 10th, 1878, and numbered 210,809, so as to constitute a part of the circuit, and, having a low conductivity and presenting a certain amount of resistance to the current of electricity, it becomes incandescent and highly luminous. If the carbon, in this condition, were exposed to atmospheric air—that is, to oxygen—it would be consumed by combustion; hence another part of the combination necessary to the result consists in filling the lamp with nitrogen gas or other gas which prevents combustion, to the exclusion of atmospheric air. The mode of doing this is pointed out in the patent No. 205,144, before referred to.

It is further stated in the specification that in the practice of the invention the applicants had made use of carbonized paper and also wood carbon; also that they had used conductors of different shapes, such as V-shaped and with rectangular corners, but preferred the arch shape, as shown in the drawings. It is added that a description of the mode of making the illuminating carbon conductors described "and making the subject-matter of this improvement" was unnecessary, as they could be made by any one skilled
in the art by the ordinary, well-known methods in practice.

4495 The specification then states the proposed practical advantages of the arched form of the conductor by its permitting the carbon to expand and contract and casting less shadow and the advantage of making the wall of the lamp wholly of glass by its preventing oxidation, leakage, &c., and states particularly the advantages resulting from the manufacture of the carbon from vegetable fibrous or textile material instead of mineral or gas carbon. "Among them," it says, "may be mentioned the convenience afforded for cutting and making the conductor in the desired form and size, the purity and equality of the carbon obtained, its susceptibility to tempering, both as to hardness and resistance, and its toughness and durability." "We have used," it is added, "such burners in closed or hermetically sealed transparent chambers, in a vacuum in nitrogen gas, and in hydrogen gas; but we have obtained the best results in a vacuum or an attenuated atmosphere of nitrogen gas, the great desideratum being to exclude oxygen or other gases capable of combining with carbon at high temperatures from the incandescing chamber, as is well understood."

The patent has four claims:

"1. An incandescing conductor for an electric lamp of carbonized fibrous or textile material and of an arch or horseshoe shape, substantially as hereinbefore set forth.

"2. The combination, substantially as hereinbefore set forth, of an electric circuit and an incandescing conductor of carbonized fibrous material included in and forming part of said circuit and a hermetically sealed chamber in which the conductor is enclosed.

4496 "3. The incandescing conductor for an electric lamp formed of carbonized paper, substantially as described.

"4. An incandescing electric lamp consisting of the following elements in combination: First, an illuminating chamber made wholly of glass, hermetically sealed, and out of which all carbon-consuming gas has been exhausted or driven; second, an electric circuit conductor passing through the glass wall of said chamber and hermetically sealed therein, as described; third, an illuminating conductor in said circuit and forming part thereof within said chamber, consisting of carbon made from a fibrous or textile material having the form of an arch or loop, substantially as described, for the purpose specified."

The great question in the suit is whether the patent sued on is valid so far as it involves a general claim for the use in electric lamps of incandescing carbon conductors made of fibrous or textile substances. If it is, the complainants must prevail. If it is not, the bill must be dismissed.

The claims of the patent (excluding the third claim, which the defendants do not use and which is not involved in the case) may be summarized as follows: (1) a conductor of carbon made of fibrous or textile material and of an arched form; (2) a conductor of carbon made of fibrous material, in a hermetically sealed chamber, without regard to form; (3) the combination of a conductor of carbon made of fibrous or textile material in an arched form and the glass chamber hermetically sealed and deprived of carbon-consuming gas. The claim of the combination last named may be dismissed from consideration as a separate claim, because a glass chamber hermetically sealed for holding the light has always been used and must necessarily be used in all incandescing carbon
4497 electric lamps. It was used by King in 1845, by Greener & Staite in 1846, by Roberts in 1852, by Konn in 1872, by Kosloff in 1875, and by others. Unless the patent is valid for the conductor of carbon made from fibrous or textile material in an arched form it cannot be made valid by combining such conductor with a glass chamber hermetically sealed.

We are equally of opinion that the giving of an arched form to the conductor was not new and could not give to the claim any validity which it would not have as a broad claim of the conductor itself made of carbon produced from a fibrous material. The arched or bent shape in incandescent conductors was applied in 1848 by Staite to an iridium conductor; in 1858 by Gardiner & Blossom to a platinum conductor, and in 1872 by Konn to a carbon conductor. In the last case the conductor was enclosed (as it had to be) in a glass lamp or case filled with nitrogen or other gas incapable of supporting combustion. The carbon, it is true, is presented in a V-shaped form, but in a similar patent, applied for a few weeks afterward, claiming the same apparatus for the production of heat, the patentee very properly says "it is evident that stems of other shapes may be used." If the U or V shaped form had not been given to carbons made of fibrous material for incandescent light before Sawyer & Man adopted that form it was merely an application by them of an old device to a new and analogous use; but the carbons used by Konn included charcoal, as well as other carbons. He mentions graphite as preferable, but he claims the use of carbons generally.

As before stated, therefore, the patent must be construed as making the broad claim to the use in electric incandescing 4498 lamps of all carbons made of fibrous or textile substances. Is the patent valid for such a broad claim? The defendants contend that it is not—first, because no such invention was set forth in the original application, but was introduced for the first time more than four years after it was filed and after the same material had been used by Edison and claimed by him in an application for a patent; secondly, because Edison, and not Sawyer and Man, was really the original and first inventor of an incandescent conductor made of fibrous or textile material for an electric lamp; thirdly, because, if Edison was not the first inventor, the thing claimed as an invention was old and neither of the parties was entitled to a patent for it.

The whole vegetable kingdom is composed of fibrous material, and all carbon or charcoal made therefrom comes within the scope of the complainant's claim. Silk is fibrous or textile, and carbon made from silk thread is therefore within the claim. Mineral coals and the carbon produced in gas retorts are not included. Can it possibly be said when we look at the history of the art of electric lighting that carbon made from fibrous or textile material was never used for that purpose until Sawyer & Man used it in 1878? We think not. We do not propose to describe in detail the various English patents of prior date which have been adduced in evidence. The word charcoal, as well as carbon, is constantly used to define the material from which the conductors were made, and that word in the English language, *prima facie*, refers to carbon or coal made of wood. We cannot yield our assent to the ingenious 4499 theory of the complainant's counsel and of some of their witnesses that the word has come to have an artificial or technical meaning in this particular art, signifying gas or mineral carbon. We think that carbon made from wood or other vegetable material is generally intended. In King's patent of 1845 he says, "The nature of the invention consist in the application of continuous metallic and carbon conductors intensely heated by the passage of a current of electricity to the purpose of illumination." * * * "When carbon is used it becomes necessary, on account of the affinity this substance has for oxygen at high temperature, to exclude from it air and moisture. To accomplish this in the most perfect manner it should be enclosed in a Torricellian vacuum." He does not confine himself to any particular kind of carbon. It is true he does afterwards say, "That form of carbon found on the

interior of coal-gas retorts which have long been used is well suited for this purpose," but his claim is general for "the application of metallic and carbon conductors intensely heated," &c., and the use of wood carbon would have infringed the patent. Greener and Staite, in their patent of 1840, in describing how they prepared the carbor for the incandescing stems in their lamps, say, "We take a quantity of lamp-black or of charcoal reduced to powder or of coke also reduced to powder, which has been purified, &c. The carbon thus highly purified we next bring into a state of great dryness, and then convert it into solid prisms or into cylinders both solid and hollow," &c. The charcoal here referred to is clearly wood charcoal. Roberts, in his patent of 1852, says, "Another part of my invention consists of a mode of obtaining electric light
by passing a current of electricity through a thin piece of
4500 graphite, coke or charcoal, or other infusible body being a
conductor of electricity, whilst it is inclosed in a vacuum or space not containing any oxygen or other matter which can cause the combustion or destruction of it when brought into an incandescent state by the action of the current of electricity. This certainly refers to wood charcoal. We have already alluded to Konn's patent of 1872, in which he claims carbon stems generally, arranged as specified in the patent for giving incandescent light. We may add that, in the earliest experiments of Sir Humphrey Davy and others on the effects of the electric current in producing light in various substances, charcoal was one of the most frequent articles used for that purpose. Long prior to 1878 it was a well-known fact in science and the arts that the transmission of the electric current through a pencil of charcoal interposed in a metallic circuit would produce intense light, and that when this charcoal was guarded from contact with oxygen in a vacuum or otherwise it would not be consumed. This is fully verified not only in scientific writings, but by the statements found in several of the patents referred to. The great desideratum was to construct an apparatus and to discover a process which would make the light economical and convenient of use for ordinary domestic purposes. We are clearly of opinion, therefore, that neither Sawyer and Man nor Edison can maintain any just claim to the exclusive use of charcoal generally in any form as an incandescing conductor in an electric lamp. This view of the subject is sufficient to decide the present case against the complainants. But there are other considerations which go to corroborate the conclusion to which we have come, which, however, we shall only cursorily examine.

4501 It is very clear to us that in the original application for the patent sued on the applicants had no such object in view as that of claiming all carbon made from fibrous and textile substances as a conductor for an incandescing electric lamp. Nothing on which to base any such claim is disclosed in the original application. We have carfully compared it with the amended application on which the patent was issued, and are fully satisfied that after Edison's inventions on this subject had been published to the world there was an entire change of base on the part of Sawyer &

Man, and that the application was amended to give it an entirely different direction and purpose from what it had in its original form. It is true that the last claim of the original was for "an illuminating arc made of carbonized fibrous or textile materials." But this claim had special reference to the arched form of the conductor rather than to the material of which it was composed; and this claim is the only expression in the application which even suggests any exclusive right to all vegetable carbons or any invention or discovery in relation thereto. No advantage in the use of said carbons is anywhere alleged. The whole scope and purpose of the application related to the arched form of the conductor. A subsidiary purpose was to claim carbon made from paper or pasteboard. They say distinctly "our improvement consists in the employment of an incandescent arc of carbon in the circuit as the light-giving medium;" "carbon" generally, not any particular carbon. By an adroit amendment made in 1885 they say: "Our improvement relates more especially to the incandescing conductor, its substance, its form, and its combination with the other elements
4502 composing the lamp." The purpose of this amendment is obvious and needs no comment. After explaining the drawings, the original application goes on to say: "Our improved burner or incandescent arc consists of an arch-shaped or semi-cylindrical piece of carbon, A, mounted in its clamps or supports in the usual well-known ways. We have tried carbonized paper covered with powdered plumbago, wood carbon or charcoal, and ordinary gas carbon. We have also used such arcs or burners of various shapes, such as pieces with their lower ends secured to their respective supports, and with their upper ends united so as to form an inverted V-shaped burner. We have also used arcs of varying contours—that is, with rectangular bends instead of curvilinear ones—but prefer the arch shape, as the shadow cast by such a burner is less than that produced by other forms of burners. We have used such burners in close transparent chambers in a vacuum, in nitrogen gas and in hydrogen gas, but have attained the best results in a vacuum or attenuated atmosphere of nitrogen, the great desideratum being to exclude oxygen from the combustion chambers, as is well understood. The operation of our improved apparatus will readily be understood from the foregoing description." Then come the claims, as follows: "First. Incandescing arcs for electric lights made of carbon, substantially as hereinbefore set forth. Second. Incandescing arcs of carbon in combination with the circuit of an electric light. Third. The combination, substantially as hereinbefore set forth, of the circuit of an electric light, an incandescing arc of carbonized paper included in the circuit, and a close transparent chamber in which the arc is enclosed. Fourth. An incandescing arc made of carbonized fibrous or textile material."

4503 This is the whole of the original application except the formal introduction. The arc is everything; the changes are rung on the arc. The fact is that Sawyer and Man were unconscious that the arc was not new, and supposed that they could get a patent for it; but as their eyes were opened they changed about and amended their application and made the material of the conductor the great object—carbon made from fibrous or textile material. Compare the original with the amended application as first stated in this opinion and this purpose most obviously appears. The carbons mentioned in the original application are merely mentioned, by the way, to show that the arched form would apply to all kinds of carbon—"We have tried carbonized paper covered with powdered plumbago, wood carbon, and ordinary gas carbon." This is changed in the amended application to the words, "In the practice of our invention we have made use of carbonized paper and also wood carbon." The object of this change is manifest. In other parts of the amended specification the importance of vegetable carbon as distinguished from gas carbon is dwelt upon. Thus they say in a former paragraph: "Our improvement consists, first, of the combination in a lamp chamber composed wholly of glass, and described in patent No. 205,144, of an incandescing conductor of carbon made from a vegetable fibrous material, in contradistinction to a similar conductor made from mineral or gas carbon, and also in the form of such conductor so made from such vegetable carbon, and combined with lighting circuit within the exhausted chamber of the lamp."

The fact that the whole object of the application was changed is evinced by the correspondence of the parties. In a
4504 letter from Wm. D. Baldwin, one of the attorneys of the applicants for the patent, to his clients, the Electro-Dynamic Light Company (who then owned the interest in the invention), dated January 8th, 1880, he says: "I have this day prepared an application for patent of arched form of incandescent carbon electric lamp made by William E. Sawyer and Albon Man, as joint inventors, containing a request for the issuing of such patent to your company, &c. * * * I will not make any alteration in the claims or specification of said patent enlarging its scope beyond its intended purpose of covering the arched or angular form of the carbon used for incandescent electric light." In a letter from Albon Man, one of the applicants for the patent, to a Mr. Cheever, dated Dec. 12th, 1880, he says: "I have received your two notes of 11th inst., enclosing the letter from the Patent Office advising Messrs. Baldwin, Hopkins & Peyton of substitution of Mr. Broadnax as attorney in carbon arch matter. This had relation to the application in question, Baldwin, Hopkins & Peyton being the solicitors in the case and Mr. Broadnax being substituted in their place. "Carbon arch matter" are words that could hardly be more suggestive.

As before stated, Edison had filed an application for a patent in December, 1879, about a month prior to the application in question, and in September, 1880, an interference was declared between the two applications. The controversy raised on this interference related principally to carbon made from paper, which Edison claimed in his application. The case was not finally decided until the beginning of 1885. Mr. Broadnax was examined as a witness in this suit and testified as follows: "After the decision of the Com-
4505 missioner of Patents of the interference awarding priority of

invention to Sawyer and Man, I resumed the prosecution of the application, insisting upon our right to the claims that had been once rejected by the examiner, among which was one for the U-shaped or loop carbon illuminant. My attention was then called for the first time by the examiner to the British patent of Konn, in which is shown an arch-shaped carbon illuminant, and which, as I thought, anticipated broadly, the claim for the U-shaped or arch-shaped carbon illuminant, and then in the discussion of the case with the examiner my attention was called to the patentability of the fibrous carbon illuminant as such on account of the properties such carbon possessed, which made it available for electric lighting above all other carbons." Being asked when this was, he said it followed soon after the decision of the Commissioner of Patents upon the question of priority or as soon as he could in the ordinary course get the case before the primary examiner again. His best recollection was that it occurred in February, 1885.

This testimony of Mr. Broadnax, which is undoubtedly to be relied on in connection with the letters just quoted, shows that the idea of claiming carbons made from fibrous and textile materials was an afterthought and was no part of the purpose of the original application. The amendments relating to this new and broad claim were made afterwards, in February and March, 1885.

We are of opinion that the changes made in the application in this regard were not justifiable, and that the claim in question cannot be sustained.

There are other aspects of the case to which we might refer
4506 which operate strongly against the claim of the complainants.

We are not at all satisfied that Sawyer and Man ever made and reduced to practical operation any such invention as is set forth and claimed in the patent in suit. Their principal experiments were made in 1878 and perhaps the beginning of 1879. The evidence as to what they accomplished in the construction of electric lamps is so contradictory and suspicious that we can with difficulty give credence to the conclusions sought to be drawn from it. We are not satisfied that they ever produced an electric lamp with a burner of carbon made from fibrous material or any material which was a success. During the year referred to, 1878, and the beginning of 1879 they applied for and obtained ten different patents (besides an English patent) on the subject of electric lamps, but not one of them contains a suggestion or a hint of any such invention as is claimed in the patent in suit, which was not applied for until 1880. They all relate to lamps with straight-pencil burners, generally of carbon, but without any preference given to one kind of carbon over another. The application for the patent in suit was not made until January, 1880, nearly or quite a year after their experiments had ceased and after the inventions of Edison had been published to the world. One cannot read the patents before applied for by Sawyer & Man, with all their detail of apparatus and process for constructing and managing the straight-stem conductors, without distinction of carbons, apparatus and processes, many of which would be needless in the lamp now claimed, without in-

dulging some degree of astonishment at the pains and ingenuity gratuitously expended or wasted if it was true that all the
4507 time they had in their possession a secret invention which would take the place of those complicated contrivances. The explanations made by the complainants for the delay in applying for the patent in suit fail to satisfy our minds that Sawyer and Man, or their assignees for them, have not sought to obtain a patent to which they were not legitimately entitled.

But suppose it to be true, as the supposed inventors and some of the other witnesses testify, that they did in 1878 construct some lamps with burners of carbon made of fibrous material and of an arched shape which continued to give light for days or weeks or months, still were they a successful invention? Would any one purchase or touch them now? Did they not lack an essential ingredient which was necessary to their adoption and use? Did they go any farther in principle, if they did in degree, than other lamps which had been constructed before? It seems to us that they were following a wrong principle—the principle of small resistance in an incandescing conductor and a strong current of electricity—and that the great discovery in the art was that of adopting high resistance in the conductor with a small illuminating surface and a corresponding diminution in the strength of the current. This was accomplished by Edison in his filamental, thread-like conductors, rendered practicable by the perfection of the vacuum in the globe of the lamp. He abandoned the old method of making the globe in separate pieces, cemented together, and adopted a globe of one entire piece of glass into which he introduced small platinum conductors fastened by fusion of the glass around them, thus being able to procure and maintain perhaps the most perfect vacuum known in the arts.

4508 In such a vacuum the slender filaments of carbon, attenuated to the last degree of fineness, may be maintained in a state of incandescence without deterioration for an indefinite time and with a small expenditure of electric force. This was really the grand discovery in the art of electric lighting, without which it could not have become a practical art for the purpose of general use in houses and cities.

It is unimportant to trace the various steps by which this great discovery was arrived at. It is well indicated and shown in Edison's patent, applied for in April, 1879, and issued May 4th, 1880, number 227,229, and is more fully described in that which he applied for November 4th, 1879, and issued January 27th, 1880, number 223,898. An extract from the latter will serve to explain the principles of this invention. Edison there says:

"Heretofore light by incandescence has been obtained from rods of carbon, of one to four ohms resistance, placed in closed vessels in which the atmospheric air has been replaced by gases that do not combine chemically with carbon. The vessel holding the burner has been composed of glass cemented to a metallic base. The connection between the leading wires and the carbon has been obtained by clamping the carbon to the metal. The leading wires have

always been large, so that their resistance shall be many times less than the burner, and, in general, the attempts of previous persons have been to reduce the resistance of the carbon rod. The disadvantages of following this practice are tha*n* a lamp having but one to four ohms resistance cannot be worked in great numbers in multiple arc without the employment of main conductors of
4509 enormous dimensions; that owing to the low resistance of
the lamp the leading wires must be of large dimensions and good conductors, and a glass globe cannot be kept tight at the place where the wires pass in and are cemented. Hence the carbon is consumed, because there must be almost a perfect vacuum to render the carbon stable, especially when such carbon is small in mass and high in electrical resistance.

"The use of a gas in the receiver at the atmospheric pressure, although not attacking the carbon, serves to destroy it in time by 'air washing,' or the attrition produced by the rapid passage of the air over the slightly coherent highly heated surface of the carbon. I have reversed this practice. I have discovered that even a cotton thread properly carbonized and placed in a sealed glass bulb exhausted to one millionth of an atmosphere offers from 100 to 500 ohms resistance to the passage of the current, and that it is absolutely stable at very high temperatures; that if the thread be coiled as a spiral and carbonized, or if any fibrous vegetable substance which will leave a carbon residue after heating in a closed chamber be so coiled, as much as 2,000 ohms resistance may be obtained without presenting a radiating surface greater than three-sixteenths of an inch; that if such fibrous material be rubbed with a plastic composed of lamp-black and tar its resistance may be made high or low according to the amount of lamp-black placed upon it; that carbon filaments may be made by a combination of tar and lampblack, the latter being previously ignited in a closed crucible for several hours and afterward moistened and kneaded until it assumes the consistency of thick putty. Small pieces of this material
4510 may be rolled out in the form of a wire as small as seven
one-thousandths of an inch in diameter and over a foot in length, and the same may be coated with a non-conducting noncarbonizing substance and wound on a bobbin or as a spiral and the tar carbonized in a closed chamber by subjecting it to high heat, the spiral after carbonization retaining its form.

"All these forms are fragile and cannot be clamped to the leading wires with sufficient force to insure good contact and prevent heating. I have discovered that if platinum wires are used and the plastic lamp-black and tar material be moulded around it in the act of carbonization there is an intimate union by combination and by pressure between the carbon and platina and nearly perfect contact is obtained without the necessity of clamps; hence the burner and the leading wires are connected to the carbon ready to be placed in the vacuum bulb. When fibrous material is used the plastic lamp-black and tar are used to secure it to the platina before carbonizing.

"By using the carbon wire of such high resistance I am enabled to use fine platinum wires for leading wires, as they will have a small resistance compared with the burner and hence will not heat and crack the sealed vacuum bulb. Platina can only be used, as its expansion is nearly the same as that of glass.

* * * * * * *

"I have carbonized and used cotton and linen thread, wood splints, papers coiled in various ways, also lamp-black, plumbago, and carbon in various forms mixed with tar and kneaded so that the same may be rolled out into wires of various lengths and
4511 diameters. Each wire, however, is to be uniform in size throughout."

The first claim of this patent is for an electric lamp for giving light by incandescence, consisting of a filament of carbon of high resistance, made as described, and secured to metallic wires as set forth. The second claim is the combination of such filaments with the receiver made entirely of glass.

Of course, the form of the filament in the receiver or globe may be varied at pleasure. It may be in the shape of a coil or of a horseshoe or it may be wound on a bobbin. All these forms are old. The principal and great thing described is the attenuated filament and its enclosure in a perfect vacuum. There may be a preference of materials from which the filament is made. Practice will evolve all these collateral advantages.

We think we are not mistaken in saying that but for this discovery electric lighting would never have become a fact. We have supposed it to be the discovery of Edison, because he has a patent for it. This may not be the case; it may be the discovery of some other person; but whoever discovered it, it is undoubtedly the great discovery in the art of practical lighting by electricity. We have given a more detailed account of it in order to illustrate what we mean when we raise the question whether the claimed inventions of Sawyer and Man were ever successful. They may have made a lamp that would burn, but was it a success or was it a failure? Did it ever go into use? What was the object of all the experiments made by them and others? Was it not to make an electric lamp that could be successfully used by the public and have a com-
4512 mercial value? Did they succeed in making such a lamp or in finding out the principle on which it could be made? We do not so read the evidence.

The bill must be dismissed.

Filed October 5, 1889.

H. D. GAMBLE, *Clerk.*

4513 *Final Decree.*

In the Circuit Court of the United States for the Western District of Pennsylvania.

THE CONSOLIDATED ELECTRIC LIGHT COMPANY *vs.* McKEESPORT LIGHT COMPANY.	No. 5. May Term, 1888. In Equity.

And now, to wit, October 10th, 1890, this cause having come on to be heard on bill, answer, replication, and proofs, and having been argued by counsel of the respective parties, it was ordered, adjudged, and decreed that the complainant's bill of complaint be dismissed at the cost of the said complainant.

BY THE COURT.

Filed October 10, 1890.

H. D. GAMBLE, *Clerk.*

4514 *Appeal.*

Circuit Court of the United States, Western District of Pennsylvania.

THE CONSOLIDATED ELECTRIC LIGHT COMPANY, Complainant, *vs.* McKEESPORT LIGHT COMPANY, Defendant.	In Equity. No. 5. May Term, 1888.

The above-named complainant, The Consolidated Electric Light Company, conceiving itself aggrieved by the order entered on October 10th, 1890, in the above-entitled proceeding, doth hereby appeal from said order to the Supreme Court of the United States, and it prays that this its appeal may be allowed, and that a transcript of the record and proceedings and papers upon which said order was made, duly authenticated, may be sent to the Supreme Court of the United States.

KERR & CURTIS,
Attorneys for Complainant and Appellant.

Pittsburgh, October 10th, 1890.

And now, to wit, on October 10, 1890, it is ordered that the appeal be allowed as prayed for.

By the court:

M. W. ACHESON, *Judge.*

Filed Oct. 10, 1890.

H. D. GAMBLE, *Clerk.*

4515 *Bond on Appeal.*

Circuit Court of the United States, Western District of Pennsylvania.

The Consolidated Electric Light Company, Complainant, vs. McKeesport Light Company, Defendant. } In Equity. No. 5. May Term, 1888.

Know all men by these presents that the Consolidated Electric Light Company, of the city, county, and State of New York, and George Westinghouse, Jr., of the city of Pittsburgh, county of Allegheny and State of Pennsylvania, are held and firmly bound unto the above-named McKeesport Light Company in the sum of five thousand dollars, to be paid to the said McKeesport Light Company; for the payment of which, well and truly to be made, the Consolidated Electric Light Company, its successors and assigns, and George Westinghouse, Jr., his heirs, executors, and administrators, and each of them, are, jointly and severally, firmly bound by these presents.

Executed and sealed with the seal of the said Consolidated Electric Light Company and of the said George Westinghouse, Jr., and dated the tenth day of October, in the year of our Lord one thousand eight hundred and ninety.

Whereas the above-named The Consolidated Electric Light Company has prosecuted an appeal to the Supreme Court of the United States to reverse the decree rendered in the above-entitled suit by the judges of the circuit court of the United States for the western district of Pennsylvania:

Now, therefore, the condition of this obligation is such that if the above-named The Consolidated Electric Light Company shall prosecute said appeal to effect and answer all damages and costs if it fail to make its said appeal good, then this obligation shall be void; otherwise the same shall be and remain in full force and virtue.

[SEAL.] THE CONSOLIDATED ELECTRIC LIGHT CO.,
By HUGH R. GARDEN, *Pres.*
GEO. WESTINGHOUSE, JR. [SEAL.]

4516 Sealed by the Consolidated Electric Light Company aforesaid and acknowledged before me — Hugh R. Garden, president of said company, this sixth day of October, 1890.

[SEAL.] JOSEPH A. WELCH,
U. S. Commissioner, Southern District of New York.

Sealed and acknowledged before me by the said Geo. Westinghouse, Jr., this 7th day of October, 1890.

[SEAL.] LORENZO C. CARUANA,
Notary Public, Kings County.

Certificate filed in New York Co.

And now, October 10th, 1890, the within bond approved.

THE CONSOLIDATED ELECTRIC LIGHT COMPANY, Complainant, *vs.* MCKEESPORT LIGHT COMPANY, Defendant.	In Equity. No. 5. May Term, 1888.

UNITED STATES OF AMERICA, *ss:*

To McKeesport Light Company:

You are hereby cited and admonished to be and appear at a Supreme Court of the United States, to be holden at Washington on the second Monday of October, 1890, pursuant to an appeal filed in the clerk's office of the circuit court of the United States for the western district of Pennsylvania, wherein The Consolidated Electric Light Company is appellant and McKeesport Light Company is repondent, to show cause, if any there be, why the judgment in the said writ of error mentioned should not be corrected and speedy justice should not be done to the parties on that behalf.

Seal of the U. S. Circuit Court, W. D. Penna.

Witness Hon. Melville W. Fuller, Chief Justice of the United States, this 10th day of October, in the year of our Lord one thousand eight hundred and ni-ety.

M. W. ACHESON,
U. S. Judge.

Attest: H. D. GAMBLE, *Clerk.*

4520 [Endorsed:] No. 5. May term, 1888. Equity. Consolidated Electric Light Co. *vs.* McKeesport Light Co. Citation. I hereby accept service of the within citation this 11th day of October, A. D. 1890. Magnus Pflaum, of counsel for defend'ts.

And now, October 11, 1890, service of the within writ accepted for the defendant company by Magnus Pflaum, Esq., of counsel for defendant, as endorsed hereon.

So ans.—

J. R. HARRAH,
U. S. Marshal.

Endorsed on cover: Case No. 14,326. W. Pennsylvania C. C. U. S. No. 286. The Consolidated Electric Light Company, appellant, *vs.* The McKeesport Light Company. Filed October 17, 1890.
